\textbf{ABSTRACT}

We present a broad–band (\(\sim 0.3–70 \text{ keV}\)) spectral and temporal analysis of \textit{NuSTAR} observations of the luminous infrared galaxy NGC 6240, combined with archival \textit{Chandra}, \textit{XMM–Newton} and \textit{BeppoSAX} data. NGC 6240 is a galaxy in a relatively early merger state with two distinct nuclei separated by \(\sim 175.\) Previous \textit{Chandra} observations have resolved the two nuclei, showing that they are both active and obscured by Compton–thick material. Although they cannot be resolved by \textit{NuSTAR}, thanks to the unprecedented quality of the \textit{NuSTAR} data at energies \(> 10 \text{ keV},\) we clearly detect, for the first time, both the primary and the reflection continuum components. The \textit{NuSTAR} hard X–ray spectrum is dominated by the primary continuum piercing through an absorbing column density which is mildly optically thick to Compton scattering \((\tau \sim 1.2, N_H \sim 1.5 \times 10^{24} \text{ cm}^{-2}).\) We detect moderate hard X–ray \((> 10 \text{ keV})\) flux variability up to 20\% on short (15 – 20 ksec) timescales. The amplitude of the variability is maximum at \(\sim 30 \text{ keV}\) and is likely to originate from the primary continuum of the southern nucleus. Nevertheless, the mean hard X–ray flux on longer timescales (years) is relatively constant. Moreover, the two nuclei remain Compton–thick, although we find evidence of variability of the material along the line of sight with column densities \(N_H \lesssim 2 \times 10^{23} \text{ cm}^{-2}\) over long (\(\sim 3–15\) years) timescales. The observed X–ray emission in the \textit{NuSTAR} energy range is fully consistent with the sum of the best–fit models of the spatially resolved \textit{Chandra} spectra of the two nuclei.

\textbf{Key words.} galaxies: active – galaxies: individual (NGC 6240) – X–rays: galaxies

1. Introduction

Galaxy mergers represent a key phase in most scenarios of galaxy formation. According to models and simulations (e.g.,...
Springel et al. 2005, Di Matteo et al. 2005, Hopkins & Elvis 2010), during the mergers of massive gas–rich galaxies, cold gas is destabilized and can rapidly form stars and will ultimately feed the active galactic nucleus (AGN). The relative importance of starbursts and AGN and the associated time scales are not known. Disentangling the contribution of these components (e.g., finding signatures of positive/negative feedback) in merging systems is crucial for comparing the observations with model predictions. In this respect NGC 6240 plays a key role as one of the nearest (\(z = 0.02448\), \(D_L = 111.2\) Mpc, \(D_A = 105.9\) Mpc) luminous infrared galaxies observed, in a relatively early merger state (Tacconi et al. 1999, Tezca et al. 2000, Bush et al. 2008, Engel et al. 2010, Medling et al. 2011). The infrared luminosity (\(L_{\text{IR}} \sim 10^{11.94}L_\odot = 3.4 \times 10^{38}\) erg s\(^{-1}\), Wright et al. 1984; Sanders et al. 2003) is at the boundary between LIRGs (luminous infrared galaxies: \(L_{\text{IR}} \geq 10^{10}L_\odot\)) and ULIRGs (ultra–luminous infrared galaxies: \(L_{\text{IR}} \geq 10^{12}L_\odot\)) and implies a high star–formation rate (SFR= \(61 \pm 30\) M\(_\odot\) yr\(^{-1}\) from Yun & Carilli 2002, through fitting of the far–infrared spectral energy distribution). Owing to the SFR which is high for its mass (e.g. Santini et al. 2009), NGC 6240 is classified as a starburst galaxy.

The definite presence of an obscured AGN in NGC 6240 has been known since the first ASCA hard X–ray observations showed that a reflection spectrum provides the best fit below 10 keV (Iwasawa & Comastri 1998). The primary emission, obscured by a column density of about \(N_H \sim 2\times10^{20}\) cm\(^{-2}\) emerges only at higher energies and was originally detected by the PDS instrument onboard BeppoSAX (Vignati et al. 1999). The nuclear intrinsic bolometric luminosity is in the quasar regime (\(L_{\text{bol}} \sim 10^{45}\) erg s\(^{-1}\), Vignati et al. 1999, Ikebe et al. 2000, Lira et al. 2002, Boller et al. 2003).

The presence of both a transmitted primary absorbed continuum and a cold reflection component is still under debate. The results obtained by the broad–band spectral analysis up to energies of 100–200 keV (Vignati et al. 1999; Ikebe et al. 2000) are controversial. Vignati et al. (1999) clearly detect the transmitted primary absorbed continuum, but the presence of the cold reflection component is not significant. On the other hand, Ikebe et al. (2000), using RXTE data, obtained an equally good fit with either a reflection–dominated spectrum or with a reflected plus transmitted model. Therefore, the presence of a primary absorbed continuum is not certain from their spectral analysis. However, Ikebe et al. (2000) concluded that both components are needed because in the pure reflection–dominated model the intrinsic power law photon index is unusually flat (\(\Gamma = 1.26 \pm 0.13\)).

Historically, NGC 6240 has shown moderate X–ray variability on month/year timescales at energies larger than \(~15\) keV \((22\pm7\%, 54\pm18\%\) and \(4\pm3\%\) in the 14–100, 14–24 and 35–100 keV Swift BAT energy bands, respectively; Soldi et al. 2013), while at softer energies it has not exhibited significant variability (Komossa et al. 1998, Netzer et al. 2005).

NGC 6240 is the result of merging of two smaller galaxies, which formed a larger galaxy with two distinct nuclei, with an angular separation of \(\sim 1.5\) \((\sim 0.7\) kpc). The two nuclei are observed in near–infrared (e.g. Fried & Schultz 1983), in the radio (e.g. Condon et al. 1982) and in optical (e.g. Rafanelli et al. 1997) images.

At X–ray wavelengths, Chandra, with its unsurpassed X–ray angular resolution (FWHM < 0·5), identified that the two nuclei are both active and both highly obscured X–ray spectra typical of Compton–thick AGN (Komossa et al. 2003). The southern nucleus is also brighter in X–rays than the northern nucleus. The observed 0.1–10 keV luminosities of the two nuclei are 1.9 \(\times10^{42}\) erg s\(^{-1}\) and 0.7 \(\times10^{42}\) erg s\(^{-1}\) (Komossa et al. 2003). The southern nucleus is also brighter based on 3–5 \(\mu\)m luminosity (see e.g. Mori et al. 2014, Risaliti et al. 2006).

The black hole mass of the southern nucleus, obtained via high resolution stellar kinematics, is \((8.4\pm 2.2) \times 10^6 M_\odot\) (Medling et al. 2011). The mass of the northern nucleus, if it follows the \(M_{\text{BH}} – \sigma\) relation (Tremaine et al. 2002), is \((1.4 \pm 0.4) \times 10^7 M_\odot\) (Engel et al. 2010). Due to the large scatter in the relation, this value is subject to systematic uncertainties much larger than the measurement errors.

The two nuclei are surrounded by extended X–ray emission modelled as a multi–temperature plasma with temperature and column density increasing toward the central regions with metal abundances that are higher than solar (\((\frac{Z}{Z_\odot}} = 2.5\)–Netzer et al. 2005; \((\frac{Z}{Z_\odot}} = 10\)–Boller et al. 2003; Wang et al. 2014). The energetics and the iron mass in the hot phase suggest that the fast shocks are due to a starburst–driven wind expanding into the ambient dense gas. Nevertheless, Wang et al. (2014) were not able to rule out additional energy injection in the circumnuclear region such as heating from an AGN outflow. High–resolution mapping of the CO(1–0) transition (Ferruglio et al. 2013a, Wang et al. 2014) revealed the presence of a molecular outflow with velocity \(\sim 200–500\) km \(s^{-1}\), originating from the southern nucleus, likely driven by both supernova winds and radiation from the AGN. Alternatively, the CO(1–0) molecular gas condenses within the outflowing gas, because the velocity difference between ionized and molecular outflows would lead to severe shredding (Veilleux et al. 2013). The coldest and outermost plasma forms a soft X–ray halo extending up to \(\sim 1.5\) from the two nuclei with sub–solar metal abundances (\((\frac{Z}{Z_\odot}} = 0.1–0.5\)–Nardini et al. 2013).

In this paper, we discuss the broad–band \((\sim 0.3–70\) keV) spectral and temporal properties of NuSTAR observations of NGC 6240 combined with archival XMM–Newton, Chandra and BeppoSAX data. In \(\S\) 2, we describe the NuSTAR and archival observations. In \(\S\) 3 we discuss the variability properties. Section 4 presents the broad–band spectral analysis, and in \(\S\) 5 we compare the individual Chandra spectra of the two nuclei with the NuSTAR spectrum of the galaxy as a whole. The results and conclusions are presented in \(\S\) 6 and \(\S\) 7, respectively.

Throughout this paper, we adopt a \(\Lambda\)CDM cosmology with \(\Omega_m = 0.27\), \(\Omega_{\Lambda} = 0.73\), and \(H_0 = 67.3\) kms\(^{-1}\) Mpc\(^{-1}\) (Planck Collaboration 2014).

\(^{1}\) \(L_{\text{IR}}\) is the \(8–1000\) \(\mu\)m luminosity according to the cosmology used in this paper.
2. X–ray observations and data reduction

2.1. NuSTAR

NuSTAR consists of two focal plane modules, FPMA and FPMB, is sensitive at 3–78.4 keV and has a FOV at 10 keV of 10′ (Harvison et al. 2013). The observatory has a 18′′ FWHM with a half–power diameter of 58″. We analyzed the NuSTAR observation of NGC 6240 performed in March 2014. The observation log is given in Table 1.

The raw events files were processed using the NuSTAR Data Analysis Software package v. 1.4.1 (NuSTARDAS). Calibrated and cleaned event files were produced using the calibration files in the NuSTAR CALDB (20150225) and standard filtering criteria with the nupipeline task. We used nuproducts task included in the NuSTARDAS package to extract the NuSTAR source and background spectra using the appropriate response and ancillary files. We extracted spectra and light curves in each focal plane module (FPMA and FPMB) using circular apertures of radius 75″, corresponding to ~ 80% of the encircled energy, centered on the peak of the emission in the 3–78.4 keV data (see Fig. 1). Background spectra were extracted using source–free regions on the same detector as the source. As shown in Table 1 the background count–rates are a low fraction (<8%) of the source count–rates.

The spectra were binned according to two criteria: (i) following the energy resolution multiplied by a factor ~0.4 at all energies, when possible; (ii) requiring a signal–to–noise ratio > 4.5. Spectral fitting was performed in the NuSTAR band alone and simultaneously with lower energy X–ray data (see below).

2.2. Chandra

Chandra, with its unsurpassed X–ray angular resolution (FWHM~0′′5), is an excellent complement to NuSTAR for analyzing the two nuclei and nearby regions and for studying possible contamination from sources that cannot be resolved by NuSTAR.

We analyzed four archival Chandra observations collected in 2001 and 2011 (see Table 2 using the Chandra Interactive Analysis Observations (CIAO) software (v.4.5; Fruscione et al. 2006) and the standard data reduction procedures. The specextract task was used to extract the spectra. The background spectra were extracted from source free regions at distances greater than about 15″ from the nuclei of the galaxy in order to avoid contamination from the X–ray diffuse emission, which is still seen on scales of 1″ (see Nardini et al. 2013). The spectra were binned to have at least 25 total counts per bin. The nuclei showed negligible pile–up (less than a few %). For the final spectral analysis, we used only the two ACIS–S observations (2001 and 2011) due to calibration uncertainties above 5 keV of HETG 0th order ACIS–S spectra.

To avoid a loss of angular sensitivity, we registered the astrometry of the ACIS–S 2001 data to the ACIS–S 2011 data, using the X–ray positions of bright common point–like sources. We found that the ACIS–S 2001 right ascension astrometric correction is –0′′1, while the declination astrometric correction is negligible (i.e. 0′′01).

From the analysis of the Chandra images (see upper panel of Fig. 2), using an aperture photometry technique (see e.g. Puccetti et al. 2009), we identified 9 serendipitous point sources with S/N ≥ 2 in the 0.3–8 keV band within/very near the area corresponding to the NuSTAR extraction region (i.e. a circle with a radius of 75″). We co–added the source spectra, background spectra and ancillary files of the nine sources with addascaspec FTOOLS v.6.13, leaving the original exposure time of a single source in the final co–added spectrum. The total 0.3–8 keV flux of these 9 sources (green spectrum in the lower panel of Fig. 2) is definitely negligible in comparison to the flux in the NuSTAR extraction region (yellow spectrum in the lower panel of Fig. 2); it is fitted by a black body of T ∼0.8 keV and there is no evidence of any iron line emission. Therefore, the co–added spectrum of the nine brightest “contaminants” is consistent with a typical spectrum of ultra–luminous X-ray sources (ULXs), which turns over very quickly at about 10 keV as discovered by NuSTAR (see e.g. Walton et al. 2015). For these reasons, we conclude that any contamination by close point–like sources in the NuSTAR spectrum is negligible.

The second step was to extract the Chandra spectra of the whole galaxy (i.e. combination of the two nuclei, extended emission and serendipitous sources) using a circular region of radius 14″/5 to maximize the S/N of the spectra. In this way, we exclude most of the very soft X–ray emission in the halo of NGC 6240 (≤ 2 keV, see Nardini et al. 2013). In any case, this component is not detectable in the energy band covered by NuSTAR, which has a low energy limit at 3 keV. This is clearly seen in the comparison of the cyan and yellow spectra in the lower panel of Fig. 2.

Finally, we verified that the whole galaxy did not show significant variations during the four Chandra observations (see Fig. 3). We used the χ² statistics with a threshold probability of 2% to test the hypothesis of constant light curves. The 0.3–8 keV light curve of the whole galaxy is consistent with being constant between the two ACIS–S and the two ACIS–S HETG observations. The 6.4–8 keV count rates are only ~0.3% and ~10% of those in the full energy band, for the ACIS–S and the zero–order ACIS–S HETG, respectively. For this reason small amplitude hard X–ray variability is difficult to detect in the full energy range; therefore we also verified that the 6.4–8 keV count rates are statistically constant. The ACIS–S and ACIS–S HETG spectra are fully consistent each other (see Fig. 4) confirming that the variability of the whole galaxy is not significant.

---

Therefore in order to improve the statistics, for the final spectral analysis we used the co-added spectra of the two ACIS–S (2001 and 2011) observations, and we also combined the corresponding background spectra, response and ancillary files. We used addascaspec: FTOOLS v6.13, which combines spectra and normalized backgrounds according to the method explained in the ASCA ABC guide.\(^3\)

In addition to the spectrum of the whole galaxy, we also used the ACIS–S spectra of each of the two individual nuclei (see Komossa et al. 2003). The spectra were extracted using circular regions centered on R.A. = 16:52:58.896, Dec. = +02:24:03.36 and R.A. = 16:52:58.922, Dec. = +02:24:05.03 and with a radius of 0″9 for the southern nucleus (the brightest one) and 0″8 for the northern nucleus, respectively (blue and red circles and spectra in the middle and bottom panel of Fig. 2). We also searched for variability in the two sub–bands: 0.3–6.4 keV and 6.4–8.8 keV. We found variability only in the 6.4–8.8 keV light curve of the northern nucleus in the ACIS–S 2011 observation ($\chi^2 = 1.84$ with probability of false positive $\leq 0.6\%$, see bottom panels of Fig. 2). Nevertheless the count rate variations are small and the median values of the count rates of the two ACIS–S observations are fully consistent (i.e. $0.011 \pm 0.001$ cts/s). Therefore we used also for the nuclei the co–added spectra of the two ACIS–S (2001 and 2011) observations. We stress that the 0.3–8 keV light curve of the northern nucleus of ACIS–S 2011 shows a systematic residual respect to a fit with a constant in the time interval 100–120 ksec in Fig. 2 which could be due to the 6.4–8 keV variability.

### 2.3. XMM–Newton

In the spectral analysis we also considered six XMM–Newton observations with a non–zero exposure time after background cleaning, obtained between September 2000 and August 2003 (see Table 2). The high spectral resolution of XMM–Newton at $\sim 6$ keV and the good counting statistics of the archival observations allow us to constrain the spectral shape and the intensity of the iron line complex. We reduced the data using the Science Analysis Software (SAS ver. 14.0.0), following the standard method described in the data analysis threads and the ABC Guide to XMM–Newton Data Analysis.\(^4\) Epochs of high background events were excluded; only events corresponding to pattern 0–12 for MOS1/MOS2 and pattern 0–4 for PN were used. From the analysis of the Chandra spectra, we found that the AGN and hot gas in the galaxy are extended less than 15″, thus the spectra were extracted using a circular region of radius 40″, which corresponds to $\sim 90\%$ of the encircled energy, similar to the NuSTAR data, which includes all the galaxy emission at energy $\geq 2$ keV. Extraction of the background spectra and binning were done similar to the NuSTAR analysis.

The whole NGC 6240 galaxy, as already pointed out by Netzer et al. (2005), does not exhibit significant spectral variability during the XMM–Newton observations (see also Fig. 5). Therefore, to improve the statistics, we considered the combination of all MOS1 and MOS2 spectra, and of the individual PN spectra. In the spectral analysis we used the XMM–Newton data between 2–10 keV only, to avoid a larger soft X–ray contribution in comparison with the Chandra spectra.

### 2.4. BeppoSAX PDS data

NGC 6240 was observed by BeppoSAX (Boella et al. 1997) on 1998 August 14 (Vignati et al. 1999) with the LECS (Low Energy Concentrator Spectrometer; 0.45–4 keV), the two MECS (Medium Energy Concentrator Spectrometers; 1.65–10.5 keV) and the PDS (Phoswitch Detector System; 15–200 keV; Frontera et al. 1997) (see Table 2). Data products were retrieved from the BeppoSAX archive at the ASI Science Data Center.\(^5\) The data were calibrated and cleaned using SAXDAS software. The MECS/LECS event files were screened adopting standard pipeline selection parameters, and the spectra were extracted from 4″ radii apertures, corresponding to $\sim 90\%$ of the encircled energy. The two MECS units were combined after renormalizing to the MECS1. The PDS is a collimator instrument with a field of view of $\sim 1°.3$ (FWHM). The PDS data were calibrated and cleaned following the standard “fixed Rise Time threshold” method for background rejection. Following the method used for the NuSTAR data, we estimate that for the MECS data, the contamination by the nearby bright sources is less than 10%. We do not use the LECS data to avoid a larger soft X–ray contribution in comparison with data from other instruments used in this work.

### 3. Light curve variability

With a few exceptions (e.g. the Compton–thick to Compton–thin changes in NGC 1365, Risaliti et al. 2005, 2007), variability in Compton–thick AGN is extremely rare at energies $< 10$ keV. Constraining intrinsic variability in such obscured sources requires statistically good sampling of the 30–50 keV energy range, where the primary continuum can arise. The analysis of the light curve in different energy ranges returns raw information on the origin of the variability (i.e., variations in Eddington ratio, column density, photon index of the primary continuum, reflection component). When data with good statistics are available, the following time/count rate resolved spectral analysis allow us to constrain better the variable spectral parameters, and place constraints on the geometry of the reflecting/absorbing medium (see e.g. NGC 4945 Puccetti et al. 2014; NGC 1068

---

* Observation identification number; † total net exposure time; ‡ start date and time of the observation interval; ‡‡ reference: 1: Vignati et al. (1999), 2: Komossa et al. (2003), 3: Nardini et al. (2013), 4: Wang et al. (2014), 5: Shu et al. (2011), 6: Boller et al. (2003), 7: Netzer et al. (2005); ‡‡ Good Time Interval after background cleaning.

Marinucci et al. submitted). Unfortunately for NGC 6240 the statistics do not allow this detailed spectral analysis.

The *NuSTAR* NGC 6240 observation lasted ~ 60 ksec, but the Earth occults the target for approximately half the orbit, yielding a net exposure time of 30.8 ksec. We analyzed the *NuSTAR* light curves in bins of 5800 s (~ 1 satellite orbit). We used the χ² and the Kolmogorov Smirnov tests to verify the constancy of the light curves. A light curve is considered definitely variable if the probability of false positive is ≤ 2% for at least one of the two tests.

The 3–60 keV light curve is slightly variable and shows a systematic trend of the residuals with respect to a fit with a constant (see Fig. 5). To investigate possible spectral variations, we analyzed the 3–10 keV and the 10–60 keV light curves separately. We found that the 3–10 keV light curve is fully consistent with being constant, but the 10–60 keV light curve is not, showing variability up to ~20%. The 3–10 keV light curve is not correlated with the 10–60 keV at a confidence level larger than 99.99% using the Spearman rank correlation coefficient. In the three energy bands, the background level is of the order of 7% of the total count rate. Moreover we verified that the source and background light curves are not correlated at a confidence level of 5%.

To better analyze the hard X–ray variability, we analyzed *NuSTAR* light curves in three narrower energy ranges: 10–25, 25–35 and 35–60 keV. We found that the amplitude of the variations is largest in the 25–35 keV energy band, changing by ~40% on timescales of ~15–20 ksec. We also searched for hard X–ray variability on similarly short timescales using the archival BeppoSAX 15–200 keV PDS data. The PDS light curve is not constant and the largest amplitude variability is ~50% on timescales of ~ 20 ksec (see Fig. 7), fully consistent with the *NuSTAR* findings.

The 20–70 keV PDS mean flux, evaluated assuming a power–law model with photon index fixed to 1.7, is a factor of ~0.9 the 20–70 keV *NuSTAR* mean flux. This factor contains...
Fig. 2: Upper panel: 0.3–8 keV image mosaic of the 2001 and 2011 Chandra observations (see Table 3). The image was smoothed with a Gaussian filter with σ = 1.5 pixels (~ 0.75′′). The big yellow circle (75′′ radius) marks the NuSTAR source extraction region; the cyan circle (14′′ radius) marks the Chandra source extraction region; the small green circles (2′′ radius) mark the 9 serendipitous point sources with S/N ≥ 2 in the 0.3–8 keV band within/very near the area corresponding to the NuSTAR extraction region. Middle panel: 6–6.5 keV image mosaic of the two Chandra observations: zoomed into the center of the galaxy: the southern nucleus and northern nucleus are marked by blue and red circles, respectively. Lower panel: Chandra spectra, unfolded with the instrument response, of the observation 12713 (see Table 3). The yellow, cyan, blue and red spectra are extracted in the regions marked with the same color in the upper and middle panels. The green spectrum represents the “contamination” spectrum by the nearby bright sources detected in the NuSTAR source extraction region. This “contamination” is negligible in the NuSTAR extraction region, whose spectrum is shown in yellow.

Fig. 4: Chandra spectra of the whole NGC 6240 galaxy, unfolded with the instrument response. The colors represent the four observations (see Table 3). Since no significant spectral variability was present, we co–added the ACIS–S spectra.

Fig. 5: XMM–Newton spectra of the whole NGC 6240 galaxy, unfolded with the instrument response. The colors represent the EPIC–PN and co–added EPIC–MOS1 and EPIC–MOS2 spectra for all the observations (see Table 3).

As shown in §2.2, we also searched for variability in the Chandra data in the hardest accessible energy range (6.4–8 keV) of the northern and the southern nuclei separately. The count rate of the 2011 ACIS–S observation of the northern nucleus is found to be variable by a factor of ~ 1.3 on timescales of ~ 15 ksec, while the southern nucleus is constant. In the two 2006 ACIS–S HETG observations we did not find statistically strong evidence of variability, neither in the southern nor in the northern nucleus. This could be due to the poorer statistics of the zero–order ACIS–S HETG data, in comparison to ACIS–S data (i.e. for the northern nucleus we had 50% fewer counts in the ACIS–S HETG).
In the 6.4–8 keV energy range, the composed light curve of the northern and southern nuclei does not present the variability shown by the northern nucleus alone. This is because the northern nucleus is a factor ~0.4 fainter, and the amplitude of its variations is small. This result is consistent with the absence of variability in the 6.4–10 keV energy range in the XMM–Newton observations.

4. Broad–band spectral analysis

4.1. The model

The extended X–ray emission at energies <5 keV in NGC 6240 is due to an absorbed multi–temperature plasma. Both the temperature and the column density increase toward the central nuclei (Boller et al. 2003, Netzer et al. 2005, Wang et al. 2014). The cold–temperature plasma, which is the outermost, extends up to ~1.5 from the nuclei, has sub–solar metal abundances (~0.1–0.5, see Nardini et al. 2013) and dominates at energies ≤1.5 keV. A medium–temperature plasma, which is less extended and is closer to the central nuclei. The hot–temperature plasma, which is dominant in the ~2–5 keV energy range, indicates the presence of fast shocks (Feruglio et al. 2013a, Wang et al. 2014, ACIS–S and HETG ACIS–S data) and is responsible for the Fe xxv line emission. In fact, while a scattered nuclear power–law would provide an equally good fit, the Fe xxv line emission is extended and spatially resolved by Chandra (Wang et al. 2014). Moreover a dominant contribution to the Fe xxv from photoionisation is ruled out through the comparison of the expected X–ray line ratios with the observed ones (Netzer et al. 2005). This is opposite to some non–LIRG AGN (e.g. NGC 1068, Bauer et al. 2015 and references therein; Circinus, Arévalo et al. 2014 and references therein), where photoionisation is dominant.

The X–ray spectrum of NGC 6240 shows line ratios between Mg xii (1.47 keV), Si xiii (1.865 keV), Si xiv (2.006 keV), S xv (2.461 keV) and S xvi (2.622 keV), due to the hot thermal component, which can be hardly reproduced within the context of equilibrium models with solar metal abundance. Therefore, to reproduce these line ratios, the hot thermal component was modelled by the XSPEC apec/mekal models with super–solar metal abundance (~2–2.5—Netzer et al. 2005; ~10—Boller et al. 2003). A more empirical approach was followed by Wang et al. (2014), who proposed a model with a mekal component, with solar abundances, plus several Gaussians to fit the residual lines. Alternatively, the observed strong emission lines are expected in non–equilibrium models, in which the ion distribution is broader than in thermal equilibrium models with the same physical conditions; in this context, Feruglio et al. (2013a) modelled the hot thermal component by a shock model with almost solar abundances. Based on these arguments, we attempted to model the hot thermal component with two different approaches: a shock model (i.e. XSPEC pshock model, hereinafter model A), and the usual mekal component (model B in the following). As shown below, the solar chemistry can be used for model A, whereas model B requires super–solar metal abundances.

In the energy range 5–8 keV the emission is mainly due to the two obscured AGN in the centre of NGC 6240 (Komossa et al. 2003). Both nuclei are best fitted with a hard, reflection–dominated spectrum and associated iron line complex (i.e. FeKα at 6.4 keV, FeKβ at 7.06 keV rest–frame energies and the Compton shoulder).

In the NuSTAR band, the two nuclei cannot be spatially resolved, and their summed contribution in the hard X–ray band is modeled as follows: a) a primary continuum, transmitted through a high column density absorber, modeled by pLCABS (Yaqoob 1997); b) a reflection component, due to optically thick gas with infinite column density illuminated by a power continuum and modeled with pEXR (Magdziarz & Zdziarski 1995).

Fig. 6: NuSTAR light curves in bins of 5800 s (~1 satellite orbit). The count rates are the added values detected by the FPMA and FPMB modules, corrected for livetime, PSF losses and vignetting, but not for background. The dotted lines correspond to the values of the count rate weighted means. The numbers in the lower left corner of each panel indicate the values of $\chi^2$ for 10 degrees of freedom, and the false positive $\chi^2$ and Kolmogorov Smirnov probabilities in the constant light curve hypothesis. From top to bottom panel: 3–60, 3–10 and 10–60 keV count rates.

Fig. 7: BeppoSAX 15–200 keV PDS light curve in bins of 10.5 ksec. The dotted line correspond to the value of the count rate weighted mean. The numbers in the top indicate the values of $\chi^2$ for 23 degrees of freedom, and the false positive $\chi^2$ and Kolmogorov Smirnov probabilities in the constant light curve hypothesis.

References
later on, we will investigate more physically realistic reflection models. The photon indices of the primary and the reflected components are linked to the same value in the spectral fits. We also added three Gaussian lines to model the FeKα, FeKβ and Nickel Kα at 7.47 keV. The FeKα and Nickel Kα are significant at 99.99% confidence level. The ratio between the normalization of the FeKβ and FeKα is fixed to the theoretical value (1:8.8; e.g. Palmeri et al. 2003). All the spectral components were absorbed by the Galactic column density along the line of sight (i.e. $4.87\times10^{20}$ cm$^{-2}$; Kalberla et al. 2005) and redshifted using $z = 0.02448$ (Downes et al. 1993). We used Anders & Grevesse (1989) cosmic abundances. For the broadband analysis, we simultaneously fit the ACIS-S (0.3–8 keV), PN (2–10 keV), MOS (MOS1+MOS2) (2–10 keV), FPMA (3–78.4 keV) and FPMB (3–78.4 keV) spectra of the whole galaxy. We introduced normalization factors to take into account the uncertain flux inter-calibration between different instruments. We fixed the normalization factor of FPMB to unity, leaving the other normalizations free to vary. As discussed above, we modeled the hot thermal components in two different ways. Therefore we used two different models, with the following XSPEC format:

Model A: 

CONSTANT$\times$WABScold$\times$(PLCABS+PEXRAV+ZGAUSS+ZGAUSS+ZGAUSS+ 
WABSmedXMEKALcold + WABSmedXMEKALmed + WABSmedXMEKALhot )

Model B: 

CONSTANT$\times$WABScold$\times$(PLCABS+PEXRAV+ZGAUSS+ZGAUSS+ZGAUSS+ 
WABSmedXMEKALcold + WABSmedXMEKALmed + WABSmedXMEKALhot )

where the subscripts cold, med, hot indicate the cold, medium and hot-temperature components, respectively.

### 4.2. Spectral analysis results

For both models A and B, the cold thermal component requires a sub–solar abundance ($\alpha < 0.2–0.5$) of the $\alpha$ elements (O, Ne, Mg, Si, S, Ar) and a lower sub–solar iron abundance ($\alpha Fe < 0.1–0.2$) at 99.97% confidence level according to an F-test. This is consistent with Nardini et al. (2013). The absorbing column density for the cold thermal component ($Nλ1 = (0.1+0.6-0.07)\times10^{22}$ cm$^{-2}$, for model A) is slightly higher than, but consistent with, the Galactic value (i.e. $Nλ1 = 0.05 \times10^{22}$ cm$^{-2}$). The column densities of the gas absorbing the medium ($kT\sim 0.9$ keV) and the hot thermal components are similar, thus are linked together in the final fits ($Nλ1 = (0.97\pm0.10)\times10^{22}$ cm$^{-2}$, for model A). This is higher than the column density of the cold thermal component. Model B requires super–solar metal abundances for the medium and hot-temperature components ($\alpha Fe < 2$).

The best–fit parameters are reported in Table 3 for both models. The parameters are fully consistent with the data ($\chi^2_{red} < 0.99$), nevertheless the quality of the fit for model B is slightly worse than for model A ($\Delta\chi^2 = +1.43$ for the same number of d.o.f.). The super–solar metallicity of the hot thermal component required by model B may indicate that the model is oversimplified. Indeed multi–temperature plasma, non–thermal plasma and X–ray binaries could contribute, with different percentages, to this component (see e.g. Bauer et al. 2015; Arévalo et al. 2014). On the other hand, the temperature of the shock in model A ($kT\sim 7.3\pm1.5$ keV) is slightly higher than the temperature obtained by fitting only the XMM–Newton spectrum ($kT\sim 5.5\pm1.5$ keV; Boller et al. 2003, Netzer et al. 2005) or the Chandra data ($kT\sim 6.15\pm0.3$ keV; Wang et al. 2014) with similar xspec models, but is consistent within the uncertainties. In fact, if the shock temperature is fixed at 6 keV the best–fit solution is still statistically acceptable. On the basis of the above described physical arguments, we chose model A as the reference model. The broadband–band best–fit spectra residuals and model A are shown in Fig. 8.

Best-fit values with uncertainties at the 90% confidence level for one parameter of interest ($\Delta\chi^2=2.706$) for model A and B. $^a$ Fixed Galactic Column Density $N_{\text{H}}$; $^b$ column density $N_{\text{H}}$ absorbing the direct power-law; $^c$ direct power-law photon index; $^d$ normalization at 1 keV of the direct power-law; $^e$ normalization at 1 keV of the reflection component; $^f$ test–frame line energy; $^g$ line equivalent width; $^h$ column density; $^i$ plasma temperature; $^j$ metal abundances; $^k$ normalization of the thermal components; $^m$ upper limit on ionization timescales. The subscripts cold, med, hot in $h, i, j, m$ and $n$ indicate the cold, medium and hot-temperature components, respectively (see § 4.1) $^n$ Normalization factors with respect to the FPMA spectrum; $^o$ intrinsic luminosities.
absorption–corrected 2–10 keV luminosity is \((7.0^{+1.8}_{-1.9} \times 10^{43})\) erg s\(^{-1}\); the reflection component in the 10–40 keV energy range is of the order of 20% of the observed primary emission.

We underline, as pointed out by Murphy & Yaqoob (2009), that combining \textsc{pexrav} and \textsc{plcabs} may produce a bias toward solutions dominated by the direct continuum. Moreover, a disc/slab geometry with an infinite column density for the material responsible for the Compton–scattered continuum is assumed in the \textsc{pexrav} model. The spectral features associated with scattering (e.g. FeK\(_\alpha\) and FeK\(_\beta\) emission lines and Compton shoulder) in a more realistic, finite column density medium cannot be reproduced by infinite slab models. The \textsc{mytorus} model\(^6\) (Murphy & Yaqoob 2009; Yaqoob & Murphy 2011, and see § 5) returns a more physically self–consistent description of the direct continuum and the reflection continuum and lines (Yaqoob & Murphy 2009, 2011, Yaqoob 2012) and it should not be affected by bias toward transmitted dominated solutions. Nevertheless, the presence in NGC 6240 of two nuclei, unresolved by \textit{NuSTAR}, makes this source not the best case for using models like \textsc{mytorus}. Therefore, for the whole galaxy we used \textsc{mytorus}\(\textit{S}\) and \textsc{mytorus\_Z}. We used the \textsc{mytorus} model in the original geometry (i.e. the so–called “coupled” mode, which represents a uniform torus with a half–opening angle of 60°, corresponding to a covering factor of 0.5). The normalization of the line component (\textsc{mytorus\_L}) is linked to that of the scattered/reflected continuum (\textsc{mytorus\_S}). The \textsc{mytorus\_L} line tables are made with a range of energy offsets for best–fitting the peak energies of the emission lines. We found that an offset of +30 eV is optimal for the northern nucleus. This energy offset is consistent with the results obtained fitting the spectra of the northern and the southern nucleus in the 5.5–8 keV energy range with an oversimplified model (i.e. empirical power–law continuum model plus redshifted gaussian lines). The FeK\(_\alpha\) energy–best–fit values are \((6.39 \pm 0.01)\) keV and \((6.42 \pm 0.01)\) keV, for the southern and northern nucleus, respectively. These values are consistent with those obtained by Wang et al. (2014, see their Table 2). The FeK\(_\alpha\) energy of the northern nucleus line is systematically higher than the theoretical value, the energy blueshift is \(20_{-12}^{+15}\) eV (conservatively the uncertainties are at the 90% confidence level for two parameters of interest, i.e. \(\Delta x = -4.61\)). This offset could take into account any residual offset due to a blend of neutral and mildly ionized iron. Alternatively, the shift could be the Doppler effect due to outflowing reflecting/absorbing medium with velocity \((-940_{-502}^{+600})\) km s\(^{-1}\) (see e.g. Elvis 2000, Risaliti et al. 2002) or residual relative motion between the two nuclei at the late stage of the merging process.

5. Resolving the two nuclei

The NGC 6240 hard X–ray emission is due to two AGN in the centre of the galaxy, resolved by \textit{Chandra} (Komossa et al. 2003) but not by \textit{NuSTAR} and \textit{XMM–Newton}. This is the first attempt to disentangle the primary emission of each nucleus by combining the spatially resolved \textit{Chandra} spectra with \textit{NuSTAR} high–energy observations.

5.1. \textit{Chandra} spectral analysis of the two individual nuclei

For this aim, we independently fitted the \textit{Chandra} spectra of the two nuclei (see § 2.2) in the 0.3–8 keV energy range. The direct and the reflection components (continuum and iron line emission) were modeled using the \textsc{mytorus} model (Murphy & Yaqoob 2009; Yaqoob & Murphy 2011).

Assuming that the direct continuum emission is a power–law, three tables are needed to generate spectral fits: \textsc{mytorus\_Z}, \textsc{mytorus\_S}, and \textsc{mytorus\_L}. \textsc{mytorus\_Z} is a multiplicative table that contains the pre–calculated transmission factors that distort the direct continuum at all energies owing to photo–electric absorption and Klein–Nishina scattering (see § 5.2 of the \textsc{mytorus} manual). \textsc{mytorus\_S} and \textsc{mytorus\_L} represent the Compton–scattered/reflected continuum toward the line of sight and the fluorescence emission lines typically produced in highly obscured AGN (i.e. FeK\(_\alpha\), FeK\(_\beta\) and Compton shoulder), respectively. We used the \textsc{mytorus} model in the original geometry (i.e. the so–called “coupled” mode, which represents a uniform torus with a half–opening angle of 60°, corresponding to a covering factor of 0.5). The normalization of the line component (\textsc{mytorus\_L}) is linked to that of the scattered/reflected continuum (\textsc{mytorus\_S}). The \textsc{mytorus\_L} line tables are made with a range of energy offsets for best–fitting the peak energies of the emission lines. We found that an offset of +30 eV is optimal for the northern nucleus. This energy offset is consistent with the results obtained fitting the spectra of the northern and the southern nucleus in the 5.5–8 keV energy range with an oversimplified model (i.e. empirical power–law continuum model plus redshifted gaussian lines). The FeK\(_\alpha\) energy–best–fit values are \((6.39 \pm 0.01)\) keV and \((6.42 \pm 0.01)\) keV, for the southern and northern nucleus, respectively. These values are consistent with those obtained by Wang et al. (2014, see their Table 2). The FeK\(_\alpha\) energy of the northern nucleus line is systematically higher than the theoretical value, the energy blueshift is \(20_{-12}^{+15}\) eV (conservatively the uncertainties are at the 90% confidence level for two parameters of interest, i.e. \(\Delta x = -4.61\)). This offset could take into account any residual offset due to a blend of neutral and mildly ionized iron. Alternatively, the shift could be the Doppler effect due to outflowing reflecting/absorbing medium with velocity \((-940_{-502}^{+600})\) km s\(^{-1}\) (see e.g. Elvis 2000, Risaliti et al. 2002) or residual relative motion between the two nuclei at the late stage of the merging process.
(see e.g. Bournaud et al. 2011). In the latter scenario, assuming the above velocity the coalescence will be in $(0.7^{+4.2}_{-0.2})$ Myr, which is shorter than the timescales of $10^{-2} - 10^{2}$ Myr estimated by other authors (see e.g. Scoville et al. 2014).

The spectra of each nucleus contain part of the X-ray emission of the circumnuclear plasma, because the hottest plasma probably originates near the nuclei. Moreover, for projection effects, the spectra can also be contaminated by the coldest plasma. Therefore, we include the multi-temperature plasma, modeled using the cold-temperature, the medium-temperature and the shock components as in model A ($\S$ 4.2), in the spectral modelling.

The XSPEC format for the adopted model for each nucleus is:

\[
\text{zpowerlaw} \times \text{mytorusZ} (\theta_{obs}) + \text{mytorusS} (\theta_{obs}) + \text{mytorusL} \times \text{wabs} \text{coldXvmekal} \text{cold} + \text{wabsmedXvmekal} \text{med} + \text{wabsph} \times \text{phshock} \text{hot}
\]

where $\theta_{obs}$ is the inclination angle between the torus polar axis and the observer’s line of sight and the photon index of the primary continuum was fixed to the best-fit value of the whole galaxy spectrum (see § 4.2 and Table 4). We performed a fit initially fixing the parameters describing the temperatures, absorption column densities and metal abundances of the three thermal components, at the best-fit values obtained for the whole galaxy spectrum (see Table 4), leaving the normalizations free to vary. Note that the normalization of the cold-temperature component for the northern nucleus is consistent with zero, while for the southern nucleus it is only ~4% of the normalization of the medium-temperature component. We do not find a statistically good description of the spectra ($\chi^2 > 2$), and some residuals are left at low energies. The best fit for the southern nucleus ($\chi^2 / \text{dof} = 1.2/7\%$) is obtained with slightly higher values of the temperature of the medium-temperature plasma component and the associated absorbing column density $(kT = (1.3 \pm 0.2) \text{ keV}, N_H = (1.5 \pm 0.2) \times 10^{22} \text{ cm}^{-2})$, as well as a higher value of the absorbing column density of the shock component $(N_H = (10 \pm 3) \times 10^{22} \text{ cm}^{-2})$. This is also the case for the northern nucleus, in which the best-fit ($\chi^2 / \text{dof} = 1.3/3.4\%$) value of the absorbing column density of the shock component is slightly higher $(N_H = (1.9 \pm 0.3) \times 10^{22} \text{ cm}^{-2})$ than that obtained in § 4.2. These results are consistent with the fact that the extended X-ray emission of NGC 6240, over a large scale, suffers from blending of thermal plasma with different temperatures, inhomogeneous absorption and metal abundance. Therefore, spatially resolved analysis in small regions can give results slightly different from the results obtained using data from larger regions (e.g. Wang et al. 2014).

The intrinsic 2–10 keV flux due to the shock component is a factor of ~6.5 larger in the southern nucleus than in the northern, consistent with the scenario that the shock originates from the southern nucleus (see Feruglio et al. 2013b, Wang et al. 2014). We also found that about 60%, 10% and 30% of the total Fe xxv line flux is emitted in the southern nucleus, northern nucleus and extended region, respectively. These percentages are consistent with those found by Wang et al. (2014) through spectral and imaging analysis.

The Chandra best-fit parameters of the primary continuum for each nucleus are reported in Table 4. For both nuclei, the inclination angle of the torus and the absorbing column density are not correlated. The inclination angle of the two tori and the absorbing column densities are different at the >99% confidence level. The equatorial $N_H$ is higher in the northern nucleus, while the inclination angle is larger in the southern one (see Fig. 9).

The Chandra best-fit values with uncertainties at the 90% confidence level for one parameter of interest ($\Delta \chi^2=2.706$).

Fig. 9: Chandra 68%, 90% and 99% confidence contours for the southern and northern nucleus: equatorial column density $N_H$ (in units of $10^{23} \text{ cm}^{-2}$) versus $\theta_{obs}$ (i.e. inclination angle between the torus polar axis and the observer’s line of sight). The confidence contours are evaluated leaving $N_H$, $\theta_{obs}$, and the normalizations of the direct continuum free to vary.

The actual line-of-sight column densities are: $N_H = (1.47^{+0.21}_{-0.18}) \times 10^{24} \text{ cm}^{-2}$ and $N_H = (1.55^{+0.72}_{-0.23}) \times 10^{24} \text{ cm}^{-2}$ for the southern and northern nuclei, respectively. For both nuclei, this is consistent with an optical depth to Thomson scattering of $\tau_T \sim 1.2$ The equivalent widths of the FeK$_x$ line (Table 3) are fully consistent with previous results (Wang et al. 2014). The intrinsic primary 2–10 keV luminosity of the southern nucleus ($5.2 \times 10^{43} \text{ erg s}^{-1}$) is a factor of ~2.6 larger than that of the northern.

Notes:
1. $\chi^2_{\text{prob.}}$ corresponds to the probability that the model fits the data within the chosen confidence level.
2. $L_{\text{sh}}$ is the intrinsic 2–10 keV flux due to the shock component.
3. $\chi^2_{\text{prob.}}$ is the probability that the model fits the data within the chosen confidence level.
4. $\Delta \chi^2=2.706$.
5. $L_{\text{sh}}$ is the intrinsic 2–10 keV flux due to the shock component.
6. $L_{\text{sh}}$ is the intrinsic 2–10 keV flux due to the shock component.
7. $\tau_T = x \times \sigma_T \times N_H$, where $\sigma_T$ is the Thomson cross section, $x$ is the mean number of electrons per H atom, which is ~1.2 assuming cosmic abundance.
In any case, these slopes are fully consistent with that obtained in the 3–70 keV energy range, and 1.09 \pm 0.08 for the northern one (\Gamma = 1.75 \pm 0.08), only a lower limit could be obtained for the northern one (\Gamma > 1.67). In any case, these slopes are fully consistent with that obtained fitting the total spectrum (\Gamma = 1.75).

6. Discussion

The two nuclei in NGC 6240 are separated by \sim 1.5 (\sim 0.7 kpc), and are therefore not spatially resolved by NuSTAR or XMM–Newton. As a first step, we performed joint NuSTAR+XMM–Newton+Chandra broad–band spectral analysis (0.3–70 keV) of the data of the whole NGC 6240 galaxy (i.e. combination of the two nuclei, extended emission and serendipitous sources), to evaluate the mean properties of the whole system and for comparison with previous high energy observations.

The broad–band 0.3–70 keV spectrum is characterized by three main spectral components (model A in §2.1 and Table 3). The first is the primary continuum emission piercing through a Compton–thick obscuring medium which dominates the spectrum at energies > 10 keV, where most of the X-ray luminosity is observed. The second component is the reflected/scattered emission from cold gas which also generates strong FeK\alpha and FeK\beta emission lines at 6–7 keV. The third is a multi–temperature thermal plasma due to the nuclear starburst and extended superwind. Both the transmitted and the reflected components are required by the best fit at a high level of significance (> 5\sigma) according to an F–test. The intensity of the reflection component in the 10–40 keV energy range is of the order of, or slightly lower, than \sim 20% of the observed primary emission. Therefore, most of the high energy flux is transmitted, rather than Compton–scattered, and the whole system is not reflection–dominated. This is consistent with the relatively low value of the FeK\alpha line equivalent width (< 0.3 keV; see also Shu et al. 2011, Brightman & Nandra 2011) and the observed variability at energies >10 keV.

The nuclear emission is characterized by a primary power law continuum with \Gamma = 1.75 \pm 0.08 and \nu L_\nu = (1.58^{+0.10}_{-0.09}) \times 10^{24} cm^{-2}, and intrinsic luminosity of (7.0^{+2.6}_{-1.6}) \times 10^{43} erg s^{-1} and of (2.18^{+0.39}_{-0.29}) \times 10^{43} erg s^{-1} in the 2–10 keV and 3–78 keV energy ranges, respectively. Our findings significantly improve upon previous BeppoSAX (Vignati et al. 1999) and RXTE (Ikebe et al 2000) results, both for disentangling the primary and reflection components, and for better constraining the spectral parameters.

The BeppoSAX best–fit absorbing column density (N_H = (2.18^{+0.39}_{-0.29}) \times 10^{24} cm^{-2}) is higher than the NuSTAR best fit value at > 3\sigma. To better investigate this discrepancy we re–analyzed the BeppoSAX data using our best–fit model A (see §2.1 and Table 3), and leaving only the column density obscuring the primary continuum free to vary. We introduced a normalization factor between our best–fit model A and the BeppoSAX data, to take into account the flux inter–calibration and the contribution from the serendipitous sources in the MECS extraction region (radius 4‘, see § 2.4). The best–fit cross–normalization factor is 1\pm 0.05. We also added a normalization factor between MECS and PDS data following the ABC BeppoSAX data analysis guide. The best–fit (\chi^2/\nu = 0.84/79\%) value of the absorbing column density is N_H = (1.82^{+0.13}_{-0.12}) \times 10^{24} cm^{-2}, which is lower, although consistent within the errors, than the Vignati et al. (1999) best fit value. The BeppoSAX best–fit N_H remains systematically higher than that of NuSTAR by about (1–2)\times 10^{23} cm^{-2}, and the bolometric luminosity is \sim 9% larger than that measured from NuSTAR. This luminosity difference includes the inter–calibration uncertainty between the NuSTAR and the BeppoSAX data, and is consistent with little intrinsic variability in NGC 6240. This would also suggest that the BeppoSAX data are not contaminated by bright serendipitous sources.

6.1. Extended emission

The NuSTAR data have made possible a precise measurement of the nuclear continuum of NGC 6240 over a broad energy range and in turn allowed better constraints on the softer components associated with the host galaxy. More specifically, the medium–temperature plasma (mekal, $kT_{\text{med}}$ in Table 3) has an observed luminosity of $2 \times 10^{41}$ erg s$^{-1}$ and ~$0.9 \times 10^{41}$ erg s$^{-1}$ in the 0.5–2 and 2–10 keV energy ranges, respectively. Star–forming galaxies are luminous sources of X–ray emission, which originates from X–ray binaries, young supernovae remnants, hot (0.2–1 keV) interstellar gas associated to star–forming regions and O stars (Fabbiano 1989, 2006 for reviews). Their X–ray luminosity correlates with the SFR (see, e.g. Ranalli et al. 2003; Lehmer et al. 2010 and reference therein), thus using the NGC 6240 SFR (61 $M_{\odot}$ yr$^{-1}$ Yun & Carilli 2002) and the relations by Ranalli et al. (2003) and Lehmer et al. (2010), we estimate a 0.5–2 keV luminosity of $2.7 \times 10^{41}$ erg s$^{-1}$ and a 2–10 keV luminosity of $0.7^{+0.9}_{-0.1} \times 10^{41}$ erg s$^{-1}$. Despite the uncertainties that affect these relations, these results suggest that the medium–temperature component can be fully due to star formation.

The hot temperature plasma ($kT_{\text{hot}}$ in Table 3) is fitted with both a non–equilibrium model (model A in Table 3) and an equilibrium model (model B in Table 3). Using model A, the ionization timescale parameter is $(4.4^{+1}_{-0.4}) \times 10^{11}$ s cm$^{-3}$. If the plasma were close to being in collisional ionization equilibrium then we would expect a value $\geq 10^{12}$ s cm$^{-3}$ (Masai 1994), suggesting that the plasma is in a marginally non–equilibrium state. The non–equilibrium model is statistically preferred over the equilibrium one ($\chi^2 = +13$ for the same number of d.o.f.). Furthermore, it does not require super–solar metal abundances, required for model B ($\chi^2 > 2$). The non–equilibrium model strongly favours the presence of a nuclear shock (Feruglio et al. 2013a, Wang et al. 2014).

For the shock component, we evaluated a best–fit value of the column density value of $N_{\text{H}} = 10^{23}$ cm$^{-2}$ and an intrinsic 0.5–8 keV luminosity of $\sim 3 \times 10^{42}$ erg s$^{-1}$. This value is about a factor of 0.5 smaller than the luminosity obtained from the Chandra spectrum only, but, as noticed by Wang et al. (2014), their absorption–corrected luminosity could be overestimated by a factor of two, given their unlike large column density of the gas obscuring the hot plasma (i.e. $N_{\text{H}} = (5.5 \pm 1.7) \times 10^{23}$ cm$^{-2}$).

6.2. AGN contribution

The total AGN bolometric luminosity, calculated assuming the bolometric corrections for type 2 AGN of Lusso et al. (2011) (~15 for the observed X–ray luminosity, with an uncertainty of a factor of ~3) and the absorption–corrected nuclear 2–10 keV X–ray luminosity, is $(1.1^{+0.5}_{-0.2}) \times 10^{45}$ erg s$^{-1}$. This value is a factor of ~2 lower than that evaluated from the spectral energy distribution (Lira et al. 2002, $L_{\text{bol}} \sim 2 \times 10^{45}$ erg s$^{-1}$, assuming the cosmology adopted in this paper). We note that Lira et al. (2002), extrapolating the best–fit of Vignati et al. (1999), assumed an AGN unabsorbed 2–10 keV continuum flux of $1 \times 10^{40}$ erg s$^{-1}$ cm$^{-2}$, which is ~ twice ours; this explains the discrepancy in the bolometric luminosity. We also note that a lower value of the total AGN bolometric luminosity reduces the discrepancy between the luminosity of the 140–K component and the absorbed AGN continuum found by the spectral energy distribution (Lira et al. 2002). Therefore, NGC 6240 is one of the most luminous among the local bona fide Compton–Thick AGN, similar to Mkn 34 (Gandhi et al. 2014).

Assuming that the 8–1000 μm luminosity of $3.4 \times 10^{45}$ erg s$^{-1}$ (Wright et al. 1984; Sanders et al. 2003) is a good proxy for the total luminosity, the two AGN contribute ~$32^{+18}_{-10}$% of the total energy output. This is consistent with the values obtained using multiple methods such as SED+Infrared spectroscopy fitting, PAH features, high/low excitation MIR lines, MIR dust continuum (e.g., 20–24%–Armus et al. 2006; 25–50%–Lutz et al. 2003; up to 60%–Egami et al. 2006; 25.8%–Veilleux et al. 2009; 45–60%–Mori et al. 2014). The AGN fraction is relatively high for the observed infrared luminosity but is not implausible. Alonso–Herrero et al. (2012) showed that in local LIRGs the AGN bolometric contribution to the IR luminosity of the system is > 25% in about 8% of the sample. Moreover, in the local Universe the AGN contribution increases with the IR luminosity of the system (Nardini et al. 2010; Inanishi et al. 2010a,b; Alonso Herrero et al. 2012), and NGC 6240 is a high–luminosity LIRG.

6.3. The accretion rate of the two nuclei

The spatially unresolved NuSTAR spectrum is consistent with the sum of the best–fit models obtained from the spectral analysis of the Chandra data of the two nuclei. This suggests that the emission at energies >10 keV of NGC 6240 is due only to the two nuclei, and is not strongly variable on long timescales (~3 years). Moreover, there are possible column density variations of $\leq 2 \times 10^{23}$ cm$^{-2}$. The two nuclei are both highly absorbed with $\tau_{7} \sim 1.2$ (i.e. $N_{\text{H}} = 1.5 \times 10^{24}$ cm$^{-2}$) and at energies >10 keV they are dominated by the primary continuum emission. The actual line–of–sight column density is a few $10^{22}$ cm$^{-2}$ larger in the northern nucleus; this would be consistent with the results from the 3–5 μm spectroscopy (Risaliti et al. 2006). The similarity of the column densities of the Compton–thick material obscuring the two nuclei could suggest that there is a common obscurer along the line–of–sight, possibly originating in gas and dust thrown up by the ongoing galaxy merger. The current data do not allow us to determine where this material lies. The calorimeter onboard the Astro–H mission (Takahashi et al. 2014) will allow to measure the profile of the FeKα with a resolution of $= 350$ km s$^{-1}$ and thus it will be possible to discriminate whether it is originated in a compact circumnuclear torus or in larger scale material in the host galaxy (Gandhi et al. 2015).

The intrinsic primary 2–10 keV luminosities of the southern (5.2 × 10$^{43}$ erg s$^{-1}$) and northern nucleus (2 × 10$^{43}$ erg s$^{-1}$) are fairly consistent, within a factor of ~2, with those expected from the MIR–X–ray luminosity correlation (Gandhi et al. 2009), using the nuclear 12 μm fluxes (Asmus et al. 2014).

The bolometric luminosities are $8 \times 10^{44}$ erg s$^{-1}$ and 2.6$ \times 10^{44}$ erg s$^{-1}$ for the southern and northern nucleus, respectively, using bolometric corrections for type 2 AGN from Lusso et al. (2011). The southern nucleus is brighter than the northern as expected according to the 3–5 μm luminosity (see e.g. Risaliti et al. 2006, Mori et al. 2014). The bolometric luminosity of the southern nucleus is lower, but consistent, with the value from the spectral energy distribution in the NIR/MIR bands ($L_{\text{bol}} = (1.4 \pm 0.6) \times 10^{45}$ erg s$^{-1}$, assuming the cosmology adopted in this paper). The slight, not significant, discrepancy could be due to a residual starburst contribution in the MIR flux.

The inferred accretion rate, $\dot{M}_{\text{Edd}} = L_{\text{bol}}/L_{\text{Edd}}$ is ~0.005$^{+0.003}_{-0.002}$ for the southern nucleus, assuming a black hole mass of (0.84–2.2)$\times 10^{8} M_{\odot}$ (Medling et al. 2011), and $\dot{M}_{\text{Edd}} = 0.014^{+0.006}_{-0.004}$ for the northern nucleus assuming a black hole mass of (1.4 ± 0.4)$ \times 10^{8} M_{\odot}$ (Engel et al. 2010). The northern nucleus shows a higher $\dot{M}_{\text{Edd}}$, but the uncertainties on its black hole mass are also a factor of a few. On the contrary, the black hole mass of the southern nu-
A detailed analysis of the light curves in several independent energy bands clearly reveals hard X–ray variability on timescales of ~15–20 ksec by up to ~20%. The variability is peaked at ~30 keV (~40%). These results are consistent with the variability detected earlier in the Swift BAT data on substantially longer timescales (i.e. months/years). In fact, Soldi et al. (2013) found maximum (54±18%) and minimum variability (4±3%) in the 14–24 and 35–100 keV energy bands, respectively. Moreover, by re–analyzing the BeppoSAX PDS data (~15–200 keV), we found variability up to ~50% on timescales fully consistent with those of the NuSTAR hard X–ray light curve. The PDS has a field of view (FOV) of 1.3° and therefore the data could suffer from contamination. Nevertheless, for NGC 6240, no known bright sources are present in the PDS FOV, and the probability of a serendipitous source in the PDS FOV with a flux equal or larger than that of NGC 6240 is ≤ 10⁻⁵ (see Vignati et al. 1999).

Assuming that the NuSTAR, BeppoSAX PDS and Swift BAT hard X–ray variability have the same origin, the observed variability can be explained by the following hypotheses:

- The variability is due to flux variations of the transmitted component of the northern nucleus up to ~20–30% for NuSTAR, and by ~50–70% for the BeppoSAX PDS and Swift BAT observed variability. Indeed, the lack of variability of the FeKα line suggests that the reflection component is constant. Moreover the spectral analysis suggests that the nuclei are transmission dominated at energies >10 keV.

- On the contrary, if the variability is due to the northern nucleus, the amplitude of the variations should be up to ~50–60% for NuSTAR, and up to of ~2.6 for the BeppoSAX PDS and Swift BAT observed variability. The NuSTAR variability would be consistent with the tentative ~30% variability in the 6.4–8 keV Chandra light curve of the northern nucleus. Nevertheless the NuSTAR, BeppoSAX PDS and Swift BAT hard X–ray variability would imply that the northern nucleus should be as bright, or brighter than the southern nucleus in some periods. This is difficult to reconcile with the evidence that over the last ~15 years, all data suggest the southern nucleus has been brighter than the northern as indicated by Chandra data (Komossa et al. 2003; Shu et al. 2011; Wang et al. 2014) and 3–5 μm luminosity (see e.g. Mori et al. 2014, Risaliti et al. 2006). Therefore the most plausible hypothesis is that the hard X–ray variability is mainly due to variations of the transmitted component of the southern nucleus.

The 6.4–8 keV tentative variability of the northern nucleus suggests changes of the direct continuum or/and of the column density; we are not able to disentangle them with the current data. In any case, the different 6.4–8 keV variability could be an indication that the matter reflecting/Compton–scattering the nuclear emission is distributed differently in the nuclei, as the result obtained in the present analysis seem to suggest (see Fig. 9).

On timescales of the order of years, the mean hard X–ray flux state is approximately constant, suggesting that the accretion rates of the two nuclei do not experience strong variability on year–long timescales.

The variability observed in NGC 6240 is similar to that observed in NGC 4945. Indeed also in NGC 4945 the hard X–ray variability is ascribed to changes of the primary continuum, confirmed through a detailed count rate resolved spectral analysis (Puccetti et al. 2014). In NGC 4945, the fast and large hard X–ray variability, the constancy of the FeKα line and the huge Compton depth along the line of sight (τc ~ 2.9) suggest a low global covering factor (~0.15) for the circumnuclear gas. In comparison with NGC 4945, in NGC 6240 the FeKα line is constant, but the hard X–ray variability is smaller and slower, likely due to the higher black hole masses and lower accretion rates, and the Compton depth along the line of sight is a factor ~2.5 lower. These findings indicate that the global covering factor for NGC 6240 should be larger than in NGC 4945.

7. Conclusion

We present NuSTAR observations of NGC 6240, one of the nearest luminous infrared galaxies in a relatively early merger state, with two distinct nuclei separated by a distance of ~ 1.5′. The main results of this work can be summarized as follows:

- We clearly detect at a high significance (> 5σ) both the transmitted primary absorbed continuum and the cold reflection continuum. The primary continuum is obscured by a NHI of ~ 1.6 × 10²² cm⁻², and dominates at energies >10 keV.

- The total AGN bolometric luminosity is (1.1±0.5) × 10⁴⁸ erg s⁻¹, which is (32±15)% of the infrared luminosity. This indicates that the galaxy emission is not dominated by the two AGN, but likely by a starburst and related processes.

- The spatially unresolved NuSTAR hard X–ray spectrum of NGC 6240 is consistent with the sum of the Chandra best–fit models of the two nuclei extrapolated to the NuSTAR hard X–ray energies. This suggests that the hard emission of NGC 6240 is only due to the two nuclei, and that it has not varied by much on a decade–long timescale. Both nuclei are highly absorbed with τc ~ 1.2 (i.e. NHI ~ 1.5 × 10²⁴ cm⁻²) as expected in the early stage of a major merger, and have bolometric luminosities ~ 8 × 10⁴⁶ erg s⁻¹ (southern nucleus) and ~ 2.6 × 10⁴⁵ erg s⁻¹ (northern nucleus). The two nuclei show low accretion rate (Lbol/Ledd is ~ 0.003 for the southern nucleus, and Ledd ~ 0.014 for the northern nucleus).

- We found variability in the NuSTAR light curve at energies >10 keV of ~20% on timescales of 15–20 ksec. We found similar variability in the BeppoSAX PDS light curve. Various arguments lead us to conclude that the hard X–ray variability is due to variations of the primary continuum of the southern nucleus.

- Finally, by comparing NuSTAR and BeppoSAX and Chandra archival data, we found that the two nuclei remain consistently Compton–thick. Although we find evidence of variability of the material along the line of sight with column densities NHI ≤ 2 × 10²⁵ on timescales of ~3–15 years.

S. Puccetti et al.: NGC 6240
Variability below 10 keV is not observed in Compton–thick AGN due to absorption and reflection. Above 10 keV only a few sources have been sampled with sufficient statistics, and NuSTAR is finding variability to be more common (NGC 4945, Puccetti et al. 2014; NGC 1068, Marinucci et al. submitted; NGC 6240, this work). Therefore to investigate variability in this type of source, good sampling of the 30–50 keV energy range is mandatory. Further NuSTAR monitoring of NGC 6240 would allow a detailed time/count rate resolved spectral analysis and help put constraints on the geometry/location of the reflecting/absorbing medium.
