Didehydroxylation – a new approach for conversion of biomass

L. Hesselholdt, R. Aniol

DTU Chemistry, Technical University of Denmark

INTRODUCTION

The available amounts of fossil fuels are rapidly diminishing while the consumption is continuously growing. Thus it is necessary to find a new source of fuel. Recently the focus on using biomass as a renewable source has increased, but while the industrial production of second generation biofuels is the best possible scenario, it does not come without challenges. First and foremost, developing a cost-effective process for conversion of biomass is a necessity. One challenge is to decrease the ratio between oxygen and carbon in the biomass in order to increase the energy density. In this project a series of initial didehydroxylation experiments has been carried out to determine the reactivity of different styrene diols as a function of their substitution pattern.

DIDEHYDROXYLATION

The osmium-catalyzed dihydroxylation of an alkene using OsO4 is a well-studied reaction whereas the didehydroxylation of a vicinal diol using Re(VI) just recently attracted attention.1

The reaction could occur via mechanism similar to the one for the dihydroxylation, just reverse. First the rhenium catalyst is oxidized to its active form, Re(VI) (fig.1), after which it reacts with the two hydroxy groups of the diol, forming an intermediate rhenium complex while releasing two water molecules. The alkene is then released, leaving rhenium in oxidation state VII. Rhenium is then reduced back to RhV by oxidation of 3-octanol.

Figure 1

Figure 1. Greenland GPS permanent stations

The results obtained for the predicted crustal uplift for KAAS is 11.62 mm/yr while the observed value was 16.321 mm/yr, for ILAS 1.74 mm/yr and 1.53 mm/yr, for QEAS -0.189 mm/yr and 1.15 mm/yr. That being a difference of 4.701 mm/yr is found for KAAS, 0.21 mm/yr for ILAS and 1.339 mm/yr for QEAS. The uncertainties associated both with the ATM and GPS results are 0.8 mm/yr for ATM and 0.5 mm/yr for GPS. The total ice mass loss in km$^3$ of water predicted from the ATM data concerning the Jakobshavn area is -88.815 between 2010 and 2005 and -83.599 between 2005 and 1997.

It seems fair to state that these differences, between the predicted and observed rates, may also be due to the fact that not all the errors have been taken into account when computing the observed results and also due to the fact that, perhaps, ice is melting in Greenland much faster than predicted.
