Targeting black mamba α-neurotoxins with nanobodies

Feared for its highly neurotoxic venom and rapid attack technique, the Black mamba (Dendroaspis polylepis) is Africa’s largest venomous snake [1]. The clinical manifestations of a bite from D. polylepis include flaccid paralysis leading to respiratory failure and death due to postsynaptic blockade of the neuromuscular junctions caused by α-neurotoxins [1-4]. Since antivenoms suffer from a reactivity bias towards larger toxins due the fact that antivenoms are produced by immunization of large mammals, current antivenoms could be reinforced by addition of monoclonal antitoxins directed towards the smaller α-neurotoxins [1-5]. Here, we report the discovery of selective nanobodies targeting α-elapitoxin Dpp2c from D. polylepis through phage display screening [6].

Results – two selective nanobody binders discovered

A M15 phage library displaying nanobody genes from a llama immunized with venom from the monocled cobra (Naja kaouthia) [7,8] was selected against a venom fraction from D. polylepis venom containing high amounts of α-elapitoxin Dpp2c. Two monoclonal phages that bound strongly to this fraction were isolated. Monoclonal phage DNA will soon be sequenced, which will unveil the primary structure of the nanobodies displayed on the phages.

Outlook – Reinforcing antivenoms with nanobodies

The isolated monoclonal nanobody displaying phages showed great selectivity towards α-elapitoxin Dpp2c and could potentially be added to existing antivenoms to reinforce their response towards this lethal α-neurotoxin. Once the sequences of the displayed nanobodies is known, the next steps include biosynthesis, determination of binding constants for the nanobodies, and measurement of their ability to inhibit α-elapitoxin Dpp2c in vitro and in vivo.
