Abstract We propose a DWDM-to-Nyquist channel conversion scheme based on complete Optical Fourier Transformation and optical Nyquist filtering. We demonstrate conversion from 50-GHz-grid 16x10 Gbit/s DPSK DWDM to a 160-Gbit/s Nyquist channel (0.9 symbol/s/Hz spectral efficiency) with 1.4 dB power penalty.

Introduction

In the past decades, dense wavelength division multiplexing (DWDM) has enabled significant increases in capacity, but this is no longer sufficient. Due to the rapid increase in Internet traffic, it is soon expected to reach the capacity of the currently installed communication systems. Recently, a Nyquist pulse technique has been proposed, which allows the signal bandwidth to be narrowed without intersymbol interference (ISI), enabling terabit/s transmission with high spectral efficiency. Over the last ten years, the time-domain optical Fourier transformation (OFT) or time lens principle has been shown to be a very versatile tool for ultrafast signal processing. It can be used for manipulating the shapes of optical signals in both the time- and frequency-domains. This has led to demonstrations of e.g. distortion-less transmission, OTDM-to-WDM conversion and all-optical OFDM transmission systems.

In this paper, we propose a DWDM to Nyquist channel conversion scheme based on complete OFT and narrow optical Nyquist filtering. Using this scheme, we convert 16 10-Gbit/s differential phase-shift keying (DPSK) channels placed on a 50-GHz DWDM grid to a 160-Gbit/s Nyquist channel with a total bandwidth of 178 GHz, thus greatly improving the spectral efficiency from 0.2 to 0.9 symbol/s/Hz. A full bit error rate (BER) characterization is performed, revealing a converted Nyquist channel with BER< 10−9 and only 1.4 dB average power penalty compared to the DWDM system. This technique could provide a simple approach to enhance the spectral efficiency of existing commercial DWDM-based systems without large system upgrades, yielding larger total system capacity.

Principle

The complete OFT is based on two quadratic phase-modulation stages (time lenses) with chirp rate K, separated by a dispersion medium of D=β2L (where β2 is 2nd order dispersion and L is length), that satisfies K=1/D. Unlike other partial OFT schemes, this configuration enables both time-to-frequency and frequency-to-time conversion at the same time, thus performing an exchange between the temporal and spectral envelopes of the input signal. The chirp rate K determines the scaling factor between the time and frequency domains according to ΔT=ΔωK.

**Experimental setup and results**

The experimental setup is shown in Fig. 1. The DWDM signal source consists of 16 distributed feedback laser diodes (DFB-LDs), centered from 1547.40 to 1553.32 nm with a 50 GHz (0.4 nm) spacing. The outputs of the CW lasers are then DPSK modulated with a 10 Gbit/s $2^{31}-1$ PRBS in a Mach-Zehnder modulator, resulting in a 16x10 Gbit/s DPSK DWDM signal placed on a 50 GHz grid as shown in Fig. 3 (a). Then, a complete OFT is used for the DWDM to Nyquist channel conversion. The quadratic phase modulation is implemented based on a four wave mixing (FWM) process in a highly nonlinear fiber (HNLF) using linearly chirped rectangular pump pulses. As a FWM pump pulse source, we use a mode-locked laser at 1557 nm, and its spectrum is broadened via self-phase modulation in a 400-m dispersion-flattened HNLF (DF-HNLF) with normal dispersion. To obtain linearly chirped pumps, the output spectrum of the DF-HNLF is filtered using a wavelength selective switch (WSS\textsubscript{1}), and each pump is subsequently propagated through an appropriate length of dispersion medium. The first pump is dispersed in a 1750 m SMF in order to convert a 50 GHz frequency grid to 6 ps temporal spacing (scaling factor $\Delta t/\Delta \omega = 19.1$ ps\textsuperscript{2}), resulting in a 55 ps chirped rectangular pump pulse. As the data signal is phase-conjugated after the first FWM process, the second pump is dispersed in a 300 m dispersion compensating fiber (DCF) having the opposite dispersion value of the 1750 m SMF, in order to achieve the same chirp rate K. The central wavelengths of the pumps are set at 1563 nm.

The first FWM output is shown in Fig. 3 (a). After extraction, the idler is dispersed in 120 m DCF, then combined with pump\textsubscript{2} and coupled into HNLF\textsubscript{2} for the second FWM process. The resulting spectrum is shown in Fig. 3(b). The generated idler is the 160 Gbit/s OTDM signal converted from the 16-channel DWDM signal. Note that the 55-ps rectangular RZ waveform obtained after the first OFT is converted to a 3.7 nm rectangular spectrum according to the scaling factor of the complete OFT. Fig. 3(c) shows the resulting OTDM waveform with 6 ps spacing, and a short guard interval between every 16 tributaries. A 166 GHz rectangular Nyquist filter implemented by WSS\textsubscript{2} is then used to filter the central part of the OTDM spectrum into a Nyquist OTDM channel as shown in Fig. 3(b). The resulting Nyquist OTDM spectrum is shown in Fig. 4(a). A 167 GHz rectangular spectrum is achieved (measured at the 6 dB level). However, due to the limited frequency resolution of the WSS, the width measured at

lower levels increases slightly (e.g. 178 GHz at the 20 dB level). Fig. 4(b) shows the Nyquist OTDM waveform, where the minimum-ISI positions are clearly observed with 6 ps spacing. These minimum-ISI positions correspond to the nulls of the sinc-shaped waveforms. The minimum-ISI position obtained in each tributary time-slot is then sampled in the NOLM, using a 1.1 ps wide control pulse for gating. Finally, the BER of each tributary is measured in a 10-Gbit/s pre-amplified DPSK receiver including a delay line interferometer (DLI) and balanced photodetection.

Fig. 5 shows the BER measurements for all 16 demultiplexed Nyquist OTDM tributaries, where error-free operation (BER<10^{-9}) is achieved for all tributaries with an average receiver sensitivity of -39.3 dBm at BER=10^{-9}. For reference, the BER performance of the original DWDM channels demultiplexed with an optical tunable filter (B2B) is also plotted in Fig. 5 (only a single channel is plotted since all DWDM channels have nearly identical BER performance). The average power penalty for all 16 tributaries at 10^{-9} is only 1.4 dB for the full system. Compared to the original signal, the converted signal bandwidth is compressed from 800 GHz to 178 GHz (20 dB level), resulting in a large spectral efficiency improvement from 0.2 to 0.9 symbol/s/Hz. Note that the optical sampling in the receiver could be replaced with a time-to-frequency converter (based on time-domain OFT) followed by optical bandpass filtering as in a standard DWDM receiver. Hence, our technique can potentially be made fully compatible with existing DWDM systems.

Conclusions

We have proposed a DWDM to Nyquist channel conversion scheme based on complete OFT and optical Nyquist filtering. A 16x10 Gbit/s DPSK, 50-GHz spacing DWDM signal was successfully converted to a 160 Gbit/s Nyquist channel with 178 GHz total bandwidth, thus increasing the spectral efficiency from 0.2 to 0.9 symbol/s/Hz (theoretical limit 1 symbol/s/Hz). The average power penalty was only 1.4 dB for the full system. This technique may provide a simple and economical solution to upgrade commercial DWDM systems.
