ABSTRACT: Well-developed genetic tools for thermophilic microorganisms are scarce, despite their industrial and scientific relevance. Whereas highly efficient CRISPR/Cas9-based genome editing is on the rise in prokaryotes, it has never been employed in a thermophile. Here, we apply Streptococcus pyogenes Cas9 (spCas9)-based genome editing to a moderate thermophile, i.e., Bacillus smithii, including a gene deletion, gene knockout via insertion of premature stop codons, and gene insertion. We show that spCas9 is inactive in vivo above 42 °C, and we employ the wide temperature growth range of B. smithii as an induction system for spCas9 expression. Homologous recombination with plasmid-borne editing templates is performed at 45−55 °C, when spCas9 is inactive. Subsequent transfer to 37 °C allows for counterselection through production of active spCas9, which introduces lethal double-stranded DNA breaks to the nonedited cells. The developed method takes 4 days with 90, 100, and 20% efficiencies for gene deletion, knockout, and insertion, respectively. The major advantage of our system is the limited requirement for genetic parts: only one plasmid, one selectable marker, and a promoter are needed, and the promoter does not need to be inducible or well-characterized. Hence, it can be easily applied for genome editing purposes in both mesophilic and thermophilic nonmodel organisms with a limited genetic toolbox and ability to grow at, or tolerate, temperatures of 37 and at or above 42 °C.

KEYWORDS: CRISPR/Cas9, bacteria, Bacillus smithii, thermophiles, genome editing, homologous recombination

Microbial fermentation of renewable resources into green fuels and chemicals is playing a major part in the development of the biobased economy. The production costs of these environmentally friendly processes have to be reduced before they become competitive with traditional fossil fuel-based industries. To this end, microbes other than the widely used model organisms, such as Escherichia coli and Saccharomyces cerevisiae, are being evaluated for their prospective abilities to act as production hosts. Thermophilic organisms are of particular interest due to their multiple advantages over mesophilic organisms when being used as production hosts. For example, their ability to grow and ferment at thermophilic temperatures reduces the cooling costs, and increase substrate and product solubility, it reduces the contamination risk with mesophiles, and there are examples of using thermophiles for nonsterilized fermentations which would reduce sterilization costs. Additionally, the fermentation process runs at the optimum temperature for enzymatic lignocellulose degradation, allowing for efficient simultaneous saccharification and fermentation. However, the use of nonmodel thermophiles as production hosts is generally hampered by the lack of well-developed genome editing tools compared to those available for currently used mesophilic model organisms.

Previous work has established basic genome editing tools for the facultative thermophilic strain Bacillus smithii ET 138 (referred to as ET 138 herein), allowing for the introduction of scar-free markerless gene deletions using homologous recombination. B. smithii grows between 37 and 65 °C and efficiently utilizes both C5 and C6 sugars. Its main product is L-lactate, and in order to use ET 138 as a versatile platform host for the production of other chemicals and fuels, its ldhL gene was deleted. No counterselection tool was used in this process, resulting in a very laborious screening process to obtain clean mutants. Subsequently, a lacZ-based counterselection was developed that relies on the toxicity of high concentrations of 5-bromo-4-chloro-3-indolyl-ß-D-galactopyranoside (X-gal). Using this system, the sporulation gene sigF and the pyruvate dehydrogenase complex subunit gene pdhA were consecutively deleted in the ldhL mutant. The resulting triple mutant strain was sporulation-deficient, which is desired in industrial fermentations for safety reasons, and did not produce L-lactate and acetate. Since the pdhA mutant was also acetate auxotrophic, the double mutant ET 138 ΔldhL ΔsigF was

selected as a basic platform strain for future studies.\textsuperscript{15} Although the lacZ-based counterselection system significantly decreased the time needed for mutant selection, the developed process is still time-consuming, with the fastest possible route to gene deletion taking approximately 2 to 3 weeks from transformation to generation of a scar-free markerless knockout.\textsuperscript{15} Moreover, the counterselection step is not stringent enough for removal of genes that are essential for the fitness and the metabolism of the strain. For the successfully engineered genes, only 12.5−33\% of the colonies had the mutant genotype, whereas for other genes, only wild-type revertants and false positives were obtained, generating mostly (66−88\%) or in some cases only wild-type revertants or false positives.\textsuperscript{15} The large number of wild-type revertants due to the absence or inefficiency of counterselection is a general issue in several nonmodel organisms.\textsuperscript{19,20} This creates the need for laborious PCR-based screening and strongly decreases throughput of the engineering process, limiting the study of these organisms and their development into industrial production hosts.

One of the fastest and most efficient methods currently available for genome editing is a system based on the Streptococcus pyogenes Cas9 (spCas9) RNA-guided DNA endonuclease of the type II CRISPR−Cas defense system.\textsuperscript{21} Jinek et al. showed that a short single guide RNA (sgRNA) molecule can direct the spCas9 endonuclease to a desired complementary target, called protospacer.\textsuperscript{22} In the presence of the short 5′-NGG-3′ DNA motif immediately downstream of the 3′-end of the protospacer, called protospacer adjacent motif (PAM), spCas9 introduces a lethal chromosomal double stranded DNA break (DSDB).\textsuperscript{22} The system was applied for genome editing of human\textsuperscript{22,23}−26 and mouse cells\textsuperscript{22} by using an inducible promoter. We create a clean gene deletion, a gene disruption, and a gene insertion by employing a plasmid-borne homologous recombination template for introduction of the desired modifications to the genome at 45 °C, and the nonedited cells are subsequently eliminated by spCas9 counterselection at 37 °C. To the best of our knowledge, this is the first time that a temperature-controlled recombination/counterselection tool has been employed for genome editing purposes, and it is the first time that a Cas9-based editing tool has been used for engineering the genome and the metabolism of a moderate thermophile.

\section*{RESULTS AND DISCUSSION}

\textbf{In Vivo Expression Validation of spCas9 at Different Temperatures.} In a parallel study, we demonstrated that the \textit{in vitro} sgRNA loading to spCas9 requires temperatures below 42 °C, which is the limiting step toward the \textit{in vitro} formation of the active sgRNA−spCas9 complex (to be published). This result motivated us to evaluate the \textit{in vivo} activity of spCas9 in ET 138 at different temperatures. We designed and constructed the modular pWUR_Cas9nt construct, which encompasses the cas9 gene of \textit{S. pyogenes} (referred to as cas9\textsubscript{sp}) and an sgRNA-expressing module for which the spacer is predicted not to target any site of the \textit{B. smithii} genome (i.e., nt, for nontargeting). The backbone of pWUR_Cas9nt is the pNW33n vector, which was the only available vector for \textit{B. smithii} (Figure 1A).\textsuperscript{15,16} The first basic requirement for the design of the pWUR_Cas9nt was the development of promoters that will drive the expression of the two components of the system: the cas9\textsubscript{sp} effector and its sgRNA guide module. For many nonmodel organisms, the number of available promoters and plasmids is very limited. ET 138 is no exception; only two promoters have been evaluated for expression in \textit{B. smithii}; the heterologous P\textsubscript{isinA} from \textit{B. coagulans} and the native P\textsubscript{Pad}.\textsuperscript{17} The latter is undesired, as integration of pNW33n-based HR plasmids into the ET 138 genome is possible\textsuperscript{15} and we want to prevent crossover events between the pWUR_Cas9nt construct and the \textit{B. smithii} genome over the promoter region. Additionally, an inducible system would be desirable. For these purposes, we tested the xynA promoter (P\textsubscript{xynA}) from \textit{Thermoanaerobacterium saccharolyticum}.\textsuperscript{18} In the genome of its native host, this promoter is induced by xylose and repressed by glucose. To test expression in ET 138, we constructed the pWUR_lacZ vector; we used pNW33n as the cloning and nontargeting). The backbone of pWUR_Cas9nt is the pNW33n vector, which was the only available vector for \textit{B. smithii} (Figure 1A).\textsuperscript{15,16} The first basic requirement for the design of the pWUR_Cas9nt was the development of promoters that will drive the expression of the two components of the system: the cas9\textsubscript{sp} effector and its sgRNA guide module. For many nonmodel organisms, the number of available promoters and plasmids is very limited. ET 138 is no exception; only two promoters have been evaluated for expression in \textit{B. smithii}; the heterologous P\textsubscript{isinA} from \textit{B. coagulans} and the native P\textsubscript{Pad}.\textsuperscript{17} The latter is undesired, as integration of pNW33n-based HR plasmids into the ET 138 genome is possible\textsuperscript{15} and we want to prevent crossover events between the pWUR_Cas9nt construct and the \textit{B. smithii} genome over the promoter region. Additionally, an inducible system would be desirable. For these purposes, we tested the xynA promoter (P\textsubscript{xynA}) from \textit{Thermoanaerobacterium saccharolyticum}.\textsuperscript{18} In the genome of its native host, this promoter is induced by xylose and repressed by glucose. To test expression in ET 138, we constructed the pWUR_lacZ vector; we used pNW33n as the cloning and expression vector, and we introduced P\textsubscript{xynA} in front of the \textit{B. coagulans}-derived lacZ gene, previously shown to be functional.

in ET 138.

Low expression was observed after overnight culture in LB2 liquid medium without an added carbon source, and strong expression was observed with both xylose and glucose (Figure S1). It is probable that the catabolite repression mechanism of ET 138 does not recognize the cre (catabolite repression element) sequence present on P

resulting in lack of transcriptional repression by glucose in B. smithii ET 138. Although P

xynA

is not tightly controllable in B. smithii, we still selected it to drive the expression of cas9 from pWUR_Cas9nt, maintaining the possibility to explore the effects of different cas9 expression levels. During all further experiments in this study, xylose and glucose were both added to the media at all of the culture temperatures to ensure constant induction of cas9 expression at all times from P

xynA

spCas9 and sgRNA modules were synthesized as one fragment, which was subsequently cloned into pNW33n through the BspHI and HindIII restriction sites. (B) To prevent double restriction sites and create a modular system, five silent point mutations (C192A, T387C, T1011A, C3126A, G354A) were introduced to the gene (depicted as *). The depicted restriction sites are unique in the construct and introduced to facilitate the exchange of genetic parts. The spacer was easily exchanged to targeting spacers via BsmBI restriction digestion or Gibson assembly. The basic construct did not contain any HR templates, but in cases where these were added, they were always inserted immediately upstream of the spCas9 module and downstream of the origin of replication. (C) Total RNA was isolated from ET 138 wild-type cells transformed with pWUR_Cas9nt or pNW33n and grown at 55, 42, or 37 °C. Six cDNA libraries were produced with rt-PCR and used as templates for PCR with cas9sp-specific primers that amplify a 255 bp region. The PCR results are depicted as follows: lane 1 corresponds to the marker (1kb+ DNA ladder, ThermoFisher), lanes 2–4 correspond to ET 138 wild-type cultures transformed with pWUR_Cas9nt and grown at 55, 42, or 37 °C, respectively, lanes 5–7 correspond to ET 138 wild-type cultures transformed with pNW33n and grown at 55, 42, or 37 °C, respectively, lanes 7, 8, 9, 11, 12 correspond to different negative controls, and lane 10 corresponds to the positive control, for which pWUR_Cas9nt was used as the PCR template.

The spCas9 expression and toxicity levels in ET 138 by transforming a single batch of competent cells with the nontargeting pWUR_Cas9nt vector and with the empty pNW33n control vector. The transformed cells were plated on LB2 plates supplemented with chloramphenicol. We incubated the plates overnight only at 55 °C, as previous incubation attempts at 37 and 42 °C were not successful (data not shown). One colony per transformation was used for the PCR. One colony was used for each PCR reaction, and the PCR results are shown in Figure 2B. The growth of the cas9-expressing cultures was similar to that of the pNW33n control cultures at all temperatures (Figure 2B), indicating that
the expression of cas9p is not toxic for ET 138 cells at any of the tested temperatures.

**In Vivo Validation of spCas9 Activity at Different Temperatures.** As the B. smithii genome encompasses genes for the basic prokaryotic NHEJ-like system,15,52 our first approach to construct a spCas9-based genome editing tool focused on determining the in vivo transformation efficiencies at spCas9 and the capacity of the ET 138 NHEJ-like mechanism to repair spCas9-induced DSDBs. We chose to target pyrF as a first proof of principle. The pyrF gene encodes the orotidine 5′-phosphate decarboxylase and is part of the operon for pyrimidine biosynthesis. Removal of the gene causes uracil auxotrophy and resistance to the toxic uracil analogue 5-fluorouracil (5-FOA). It is a frequently used selection and counterselection system.

Removing the uncharacterized nature of P. smithii ET138 ΔldhL ΔsigF strain.15 This strain is sporation-deficient, it cannot produce L-lactate, and it was constructed as the basic platform strain for further metabolic engineering work. We obtained similar results as those for the wild-type B. smithii ET138 strain (Figure S3), and we continued our study using the double mutant strain.

In line with the in vitro assay data, the aforementioned results indicate that the designed spCas9 system is active at 37 °C but inactive and does not introduce lethal DSDBs to the ET 138 genome at temperatures from 42 °C and above. It also indicates that the NHEJ system in ET 138 is inactive at 37 °C or not active enough to counteract the spCas9 activity. In addition, the sequencing results of the pWUR_Cas9sp2 construct revealed the deletion of seven nucleotides near the 3′ end of P_pla (Figure S2). However, the results of the targeting experiment support our hypothesis that the uncharacterized nature of P_pla and possibly the extra nucleotides at the 3′ end of the sgRNA module, does not hinder the targeting efficiency of spCas9. Moreover, the truncated P_pla of the pWUR_Cas9sp2 construct clearly expresses enough sgRNA molecules, and the observed seven-nucleotide long deletion has no impact to the targeting efficiency of the corresponding spCas9 sgRNA complex. The latter two observations reveal that our system tolerates a certain level of flexibility in the 5′-extension of the sgRNA molecule.

**Efficient Gene Deletion Using a HR-CRISPR–Cas9 Counterselection System.** Taking into account the results described so far, we decided to develop a Cas9-based editing system for ET 138 that exploits its efficient homologous recombination mechanism17 and the temperature-induced spCas9 activity at 37 °C. The new experimental setup consists of a single plasmid that combines the recombination template
Figure 3. Schematic representation of the different homologous recombination and spCas9-mediated mutations described in this study. The first single crossover event (SCO) can occur by insertion of the editing plasmid into the chromosome either through the upstream homologous region (UHR), as depicted here, or through the downstream homologous region (DHR). (A) Gene deletion. A scar-less, markerless pyrF gene deletion was established after insertion of the editing vector into the chromosome via homologous recombination with the plasmid-borne editing template (2 × 1 kb flanks, immediately flanking the pyrF gene and thus removing it from start to stop codon), after which a second SCO event results in either wild-type revertants or edited cells. The spCas9 targeting of the wild-type cells acts as counterselection for the pyrF mutants. (B) Gene knockout via insertion of stop codons and a restriction site. The followed process was similar to the gene deletion described above. The hsdR restriction gene was inactivated by inserting stop codons and a restriction site between codons 212 and 221 that were contained in a 2 kb HR fragment that expands 289 bp upstream and 1.65 kb downstream from the start codon of the hsdR gene on the genome of the ET 138. Between the two stop codons, an EcoRV restriction site was added, generating a frame shift and facilitating the screening process. The spacer was designed to target the original sequence without stop codons and restriction site. (C) Gene knock-in. The followed process was similar to the gene deletion and gene knockout processes described above. The ldhL gene was reinserted into mutant strain ET 138 ΔldhL ΔsigF. This was achieved by adding the original ldhL gene sequence between 2 × 1 kb HR flanks. The spacer was designed to target the area between the ldhL stop codon and the beginning of the adjacent rho-independent transcriptional terminator. On the HR flanks, the region between the ldhL stop codon and its rho-independent transcriptional terminator was inverted, avoiding the spCas9 targeting of edited cells.
and the spCas9- and sgRNA-expressing modules. Providing the cells with the appropriate plasmid-borne editing template at 55 °C and then inducing the expression of active spCas9 at 37 °C through a sequential culturing process is expected to form a powerful homologous recombination and counterselection system. To generate a pyrF deletion mutant, pWUR_Cas9sp1 was selected as the pyrF-targeting vector for further experiments, which was always compared to the nontargeting control, pWUR_Cas9nt. To both vectors, we added a fusion of the two pyrF flanks (each 1 kb), creating the pWUR_Cas9nt_hr and pWUR_Cas9sp1_hr vectors (i.e., hr, for homologous recombination) (Figure 3A). After transforming the four constructs (two with flanks and two without flanks) into ET 138 ΔldhL ΔsigF at 55 °C, one verified transformant per construct was inoculated into TVMY selection medium containing xylose and glucose and supplemented with uracil (TVMYxgu) to complement the auxotrophy in the case of successful pyrF deletion. After growth at 55 °C for 24 h, cells were sequentially transferred every 24 h to fresh media while gradually decreasing the culturing temperature from 55 to 37 °C, with an intermediate transfer at 45 °C. After three more transfers at 37 °C to allow for efficient spCas9 counterselection, cells were transferred back to 55 °C with an intermediate transfer at 45 °C, allowing for gradual adjustment of their metabolism. As expected, PCR on genomic DNA from the pWUR_Cas9nt and pWUR_Cas9_sp1 cultures showed no pyrF knockout bands at any culturing temperature due to the lack of a homologous recombination template in the constructs. In line with the initial in vivo tests, pWUR_Cas9_sp1 cultures at 37 °C showed almost no growth, whereas the pWUR_Cas9nt cultures at all temperatures showed the expected growth for ET 138. PCR on genomic DNA from the liquid cultures containing the vectors with pyrF flanks showed the absence of knockout bands for the pWUR_Cas9nt_hr cultures from the first culturing step at 37 °C onward, but very strong pyrF knockout bands for the pWUR_Cas9sp1_hr cultures for the same culturing steps mentioned above (Figure 4A). The striking difference in the density of the knockout bands between the targeting pWUR_Cas9sp1_hr and the nontargeting pWUR_Cas9nt_hr cultures indicates successful spCas9 activity and pyrF targeting by the pWUR_Cas9sp1_hr construct. It furthermore indicates that the counterselection activity of spCas9 is already efficient at 37 °C. Growth of the pWUR_Cas9nt.hr cultures was similar to the control at all temperatures, whereas the pWUR_Cas9sp1_hr cultures showed poor growth in the first two culturing steps at 37 °C, but the growth was reconstituted to control levels from the third culturing step at 37 °C onward (Figure S4). After an upshift in the temperature, colony PCR of the 55 °C colonies showed that 5 out of 10 tested pWUR_Cas9sp1_hr colonies were pure pyrF deletion mutants, i.e., an editing efficiency of 50% for our system (data not shown). The correct mutations were also verified by sequencing. None of the 10 tested pWUR_Cas9nt_hr colonies (nontargeting control) were pyrF deletion mutants, demonstrating functional spCas9 targeting.

Figure 4. (A) Agarose gel electrophoresis showing the results from PCR on the genomic DNA of a ET 138 ΔldhL ΔsigF culture transformed with pWUR_Cas9sp1_hr and sequentially transferred to different temperatures (following the depicted temperature sequence) for detection of pyrF deletion mutants in the culture mixture. The pyrF deletion mutant band appears from the first 37 °C culturing step (lane 3) onward. The last 2 lanes are the negative (wild-type) and positive (ΔpyrF) controls, which correspond to 2.9 and 2.1 kb DNA fragments, respectively. (B) Agarose gel electrophoresis showing the resulting products from colony PCR on colonies transformed with pWUR_Cas9sp1_hr for the detection of deletion mutants. Nine out of the 10 tested colonies (S.C.#1 to S.C.#10) that resulted from the 3-day long editing process in TVMYxgu (TVMY supplemented with xylose) medium were deletion mutants. The last 2 lanes are the negative (wild-type) and positive (ΔpyrF) controls, respectively.
To improve the efficiency and speed of the system, we repeated the process for the pWUR_Cas9sp1_hr-containing strain and reduced the number of culturing steps at 37 °C from 4 to 1 while keeping the culturing time of each step in a window between 8 and 16 h. Moreover, we used three different media in order to observe possible medium-dependent variations in the efficiency of the system: TVMY selection medium supplemented with xylose, glucose, and uracil (TVMY$_{xyg}$); TVMY selection medium supplemented with xylose and glucose but not with uracil (TVMY$_{xyg}$); and LB2 medium supplemented with xylose and glucose (LB2$_{xyg}$). After the final culturing step at 55 °C, cells were plated on selective agar of the corresponding medium, supplemented with uracil. Colony PCR on 10 randomly selected colonies for each medium and construct showed that 9 out of 10 colonies were pure pyrF deletion mutants colonies from the culturing process on TVMY$_{xyg}$ medium (Figure 4B). From the process with TVMY$_{xyg}$ medium, 4 of the examined colonies were pure pyrF deletion mutants, proving the efficiency of the counterselection tool even in the presence of an auxotrophy barrier (Figure 4B). The process with LB2$_{xyg}$ medium was repeated twice, with two different pWUR_Cas9sp1_hr containing ET 138 clones. Surprisingly, all colonies evaluated from the LB2 medium process (40 in total) contained the wild-type pyrF gene (data not shown). At this moment, it is unclear as to what causes this difference between the LB2$_{xyg}$ medium and the two types of TVMY media, and this will be addressed in future research.

To retain spCas9 activity, antibiotics were added in all steps. To allow for subsequent metabolic engineering steps, however, plasmid curing is required. After transferring a sequence-verified pyrF deletion mutant twice in TVMY medium without antibiotics, cells were plated on TVMY plates without antibiotics. Colony PCR with plasmid-specific primers showed that all eight tested colonies had lost the plasmid. Finally, we verified the 5-FOA sensitivity and the uracil auxotrophy of two ET 138 ΔldhL ΔsigF ΔpyrF cultures that originated from two of the tested colonies ET 138 (Figure S5).

**Expanding the Toolbox: Knocking Out the Type I RM System.** To increase the potential of ET 138 as a platform organism for the production of green chemicals, we aimed to improve its transformation efficiency. ET 138 has a type I restriction-modification (R-M) system. Methylation analysis of the PacBio genome sequencing data showed the existence of the single motif “Cm6AGNNNNNTGT/ACm6ANNNNN-NCTG” with N6-methyladenine (m6A) modifications (unpublished data). Our attempts to transform different pNW33n-based constructs containing one or multiple copies of this motif were unsuccessful or gave 3-orders of magnitude lower transformation efficiencies compared to those with constructs of the same size that do not contain the aforementioned motif. We decided to knock out the hsdR restriction gene of the B. smithii ET138 type I R-M system, expecting to overcome the transformation obstacle and further expand its genetic accessibility.

For knocking out the hsdR gene, we followed a different approach compared to the pyrF deletion process to evaluate the efficiency of the Cas9-based counterselection editing method in the introduction of limited-sized modifications to the genome. Between the origin of replication (or) and the cas9$_y$ gene of the pWUR_Cas9nt vector, we introduced a 1920 bp HR fragment that resulted from the fusion of two separate fragments: one that is composed of the 924 bp upstream of codon 212 of the hsdR gene (including the two first nucleotides of the codon) and one that is composed of the 986 bp downstream of codon 221 of the hsdR gene. In this HR fragment, we replaced the 25 nt part between codons 212 and 221 of the hsdR gene, including the last nucleotide of codon 212, with an 8 nt sequence composed of two stop codons and an EcoRV restriction site, generating a frame shift and facilitating the screening process (Figure 3B). Since the hsdR gene is 2952 nucleotides (984 codons) long, only one-fifth of it
will be translated due the introduction of the stop codons. We also introduced a spacer in the sgrRNA module for spCas9 targeting of the unmodified genomes, completing the construction of the pWUR_Cas9spKI_hr editing vector.

*B. smithii* ET138 ΔldhL ΔsigF cells were transformed with the new vector and sequentially cultured as before, gradually decreasing the temperature from 55 to 37 °C, with an intermediate transfer at 45 °C, and then increasing it back to 55 °C. The duration of each culturing step was within a window of 8 to 16 h. Moreover, we used two types of selection media, LB2xg and TVMYxg. Five transformants per medium were subjected to colony PCR, after which the PCR fragments were digested with EcoRV. All colonies from the LB2-culturing process were successfully modified (Figure 5A), giving 100% editing efficiency, whereas only two of the colonies from the TVMY process were modified, giving 40% editing efficiency (Figure 5B). This is in contrast with the result from the pyrF deletion process, where there were no modified colonies resulting from the LB2-culturing process. This suggests that the selection of culturing medium influences the efficiency of our editing system in a variable and gene-specific manner. Plasmid curing was performed as before, and the correct mutations were verified by sequencing.

We confirmed the lack of a functional R-M system in the newly developed ET 138 ΔldhL ΔsigF ΔhisdR strain by successfully transforming the plasmid-cured cells with vector pG2K (Table S2). In previous attempts, we did not succeed in transforming this vector into other (hisdR+) ET 138 strains as it contains the aforementioned methylation motif in its antibiotic resistance marker gene, the kanamycin nucleotidyltransferase (aadA) gene derived from *Geobacillus stearothermophilus*. In this way, we added a new antibiotic resistance marker to the toolbox of ET 138, and we confirmed that the ET 138 ΔldhL ΔsigF ΔhisdR strain can be utilized for the expansion of the genetic parts toolbox.

**Metabolic Engineering Using spCas9: Knock-In of the ldhL Gene.** Next, we evaluated the applicability of our Cas9-based system in markerless gene chromosomal integrations by knocking the 942 bp long genomic fragment between the start and stop codons of the lactate dehydrogenase (*ldhL*) gene into the genome of ET 138 ΔldhL ΔsigF ΔhisdR. The reconstitution of lactate production in the resulting ET 138 ΔsigF ΔhisdR strain would allow for efficient growth under anaerobic conditions, while retaining the advantages of a sporulation- and R-M-deficient strain.

Two versions were constructed of a pWUR_Cas9ΔldhLΔsigFΔhisdR vector that target the ET 138 ΔldhL ΔsigF ΔhisdR genome at the same position between the *ldhL* stop codon and the beginning of the adjacent rho-independent transcriptional terminator. HR was facilitated with 1 kb flanks (pWUR_Cas9spKI_hr1) or 0.75 kb flanks (pWUR_Cas9spKI_hr2). For both versions, the region between the *ldhL* stop codon and its rho-independent transcriptional terminator was inverted, avoiding spCas9 targeting (Figure 3C). Wild-type *ldhL* sequence was inserted in the region between the start and stop codons to allow it to be knocked in.

ET138 ΔldhL ΔsigF ΔhisdR was transformed with the two pWUR_Cas9ΔldhLΔsigFΔhisdR versions, and the transformants were sequentially cultured as described before, gradually decreasing the temperature from 55 to 37 °C, with or without an intermediate transfer step at 45 °C, and then increasing it back to 55 °C. Each culturing step was within a window of 8 to 16 h. Again, we used two types of selection media, LB2xg and TVMYxg. The colony PCR results of the TVMY culturing processes showed that none of the tested colonies had the knock-in genotype. The colony PCR results of the LB2 culturing processes with the pWUR_Cas9spKI_hr1 transformant showed that with the additional culturing step at 45 °C, 4 out of the 20 tested colonies had the knock-in genotype (20% editing efficiency), 15 colonies had a mixed knock-in/wild-type genotype, and only 1 colony had the wild-type genotype (Figure 6A). When the culturing step at 45 °C was omitted, only 1 out of the 20 tested colonies had the knock-in genotype, 11 colonies had the mixed genotype, and 8 colonies had the wild-type genotype (Figure 6B). The colony PCR results of the LB2 culturing processes with the pWUR_
Cas9spKI hr2 transformant showed that with the additional culturing step at 45 °C, 1 out of the 20 tested colonies had the knock-in genotype (5% editing efficiency). 7 colonies had the mixed knock-in and wild-type genotype, and only 1 colony had the wild-type genotype (Figure S6A). When the culturing step at 45 °C was omitted, none of the 20 tested colonies had the knock-in genotype, only 6 colonies had the mixed genotype, and the remaining 14 colonies had the wild-type genotype (Figure S6B). This was the first time that we observed colonies with a mixed genotype using our editing approach. The appearance of such colonies could be explained by relatively inefficient Cas9 targeting when the enzyme is loaded with a suboptimal sgRNA module, as has been described for E. coli, although the molecular basis for this phenomenon remains elusive. Alternative sgRNAs may lead to a more stringent counterselection, thereby improving the editing efficiency. Additionally, the difference in recombination efficiency at specific chromosomal sites might influence the editing efficiency of the tool. In a recent study that combined dsDNA recombineering with Cas9 counterselection, the efficiency of the employed system for insertions was lower than the efficiency for deletions, whereas longer homologous regions led to higher editing efficiencies. Our results confirm the influence of the HR template length and the importance of the culturing period before the induction of counterselection. The editing efficiency of the tool was higher when we employed the editing construct with the 1 kb HR flanks compared to the editing construct with the 0.75 kb HR flanks (20 vs 8% efficiency, respectively; Figure S6). Furthermore, we observed that a culturing period with an additional intermediate step at 45 °C allows for efficient homologous recombination and double crossover events to occur, leading to the appearance of the mutants for which Cas9 will select. This is in line with observations in Lactobacillus reuteri and supports our findings that the efficiency of using spCas9 as a counterselection tool is higher compared to that using spCas9 as a tool for the induction of the cellular HR mechanism after introduction of targeted DSBs. In addition, it may be that the stress of decreasing the temperature increases the efficiency of the homologous recombination mechanism.

Next, we attempted to cure the constructed B. smithii ET138 ΔsigF ΔhsdR strain from the pWUR_Cas9spKI hr1 plasmid using the sequential transferring approach in LB2 medium without antibiotic at 55 °C. However, after the usual two transfers, none of the tested colonies had lost the plasmid. We repeated the same sequential transferring process but increased the culturing temperature to 65 °C, as the pNW33n replicon might be less stable at elevated temperatures. After two transfers at 65 °C, 1 out of 8 tested colonies was confirmed to be plasmid-free by PCR and antibiotic sensitivity, and the correct mutations were verified by sequencing. Plasmid curing might be simplified in the future by adding an sgRNA expressing module with a spacer against the editing plasmid to the system. The module will have to either be under the control of a tightly inducible promoter or cloned into a second expression vector and transformed into the edited cells in a second transformation round.

Finally, evaluation of lactate production in the resulting B. smithii ET138 ΔsigF ΔhsdR strain under aerobic, microaerobic, and anaerobic conditions showed a complete restoration of lactate production to wild-type levels (Table S4).

## CONCLUSIONS

In this study, spCas9-based genome editing was applied for the first time to a moderate thermophile, establishing a gene deletion, a gene knockout, and a gene insertion. A major advantage of this system is the requirement of only one plasmid without inducible or highly characterized promoters to drive spCas9 and sgRNA expression. Additionally, the speed and efficiency of the genome editing process of ET 138 has been substantially improved compared to that of the previous lacZ-based counterselection system. For the three cases presented in this study, it took on average 1 week from transformation to clean deletion, knock out, or knock in (including the plasmid curing step), with an editing efficiency of 90% for the gene deletion, 100% for the gene knock out, and 20% for the gene insertion.

Over the course of our study, we showed that spCas9 is not active in vivo from 42 °C and above. This observation allowed us to develop an editing system where mutants are constructed via homologous recombination events at higher temperatures (≥42 °C) before Cas9-induced counterselection takes place at 37 °C. The crucial factors for obtaining high editing efficiencies are giving sufficient time for HR at elevated temperatures before starting the spCas9-based counterselection, and the length of the HR flanks. Moreover, we hypothesize that testing different sgRNA modules may improve the editing efficiency of the tool. During our study, we observed gene-dependent differences in the number of obtained mutants when repeating the same process using different media. There is no obvious link between the editing of a specific gene and the medium used for the editing process, and this will be the subject of further studies.

The results of the editing approach that we developed make our system potentially applicable for many interesting model or nonmodel organisms with an active HR mechanism and a growth temperature range covering 37 to ≥42 °C. It is anticipated that the approaches reported here will expand the range of organisms for which the powerful Cas9 counterselection tool can be used, thereby greatly increasing engineering throughput for these organisms and allowing for both their fundamental study and biotechnological exploitation.

## MATERIALS AND METHODS

### Bacterial Strains and Growth Conditions.

Strains used in this study are listed in Table S1. All B. smithii strains were routinely cultured at 55 °C unless stated otherwise. TVMY medium and LB2 medium were used as described previously. TVMY<sub>xy</sub> is TVMY supplemented with 0.5 g/L xylose, 0.5 g/L glucose, and 50 mg/L uracil. TVMY<sub>sg</sub> is TVMY supplemented with 0.5 g/L xylose and 0.5 g/L glucose. LB2<sub>sg</sub> is LB2 supplemented with 0.5 g/L xylose and 0.5 g/L glucose. Substrates were added separately as 50% autoclaved solutions after autoclaving the medium. Uracil was added as a 50 mg/mL filter sterilized solution in 1 M NaOH after autoclaving the medium and addition of the substrates. E. coli strains were grown in LB medium at 37 °C. For plates, 30 g of agar (Difco) per liter of medium was used for B. smithii in all experiments; 15 g of agar (Difco) per liter of LB was used for E. coli. If required, chloramphenicol was added at concentrations of 25 μg/mL for E. coli DH5α, 15 μg/mL for E. coli TG90, and 7 μg/mL for B. smithii.

### Genomic DNA Isolation, Transformations, Colony PCR, Sequencing, and Phenotypic Verification.

Genomic
DNA from \textit{B. smithii} strains was isolated using the MasterPure Gram positive DNA purification kit (Epicenter). Heat shock transformation of \textit{E. coli} strains was performed according to the supplier’s protocol. Transformation of \textit{B. smithii} strains was performed as described previously.\textsuperscript{15} Plasmids for transforming \textit{B. smithii} were extracted from \textit{E. coli} via maxiprep isolation (Genomed Jetstar 2.0). For transformation of \textit{B. smithii} strains, 1 \(\mu\)g DNA was used unless it is stated otherwise in the plasmid construction sections.

Potential \textit{B. smithii} ET138 \(\Delta\text{ldhL}\ >\Delta\text{sigF}\ >\Delta\text{pyrF}\) colonies were randomly selected and subjected to colony PCR using the InstaGene Matrix (Bio-Rad), Taq DNA polymerase (NEB), and genome-specific primers BG6420 and BG6421. Potential \textit{B. smithii} ET138 \(\Delta\text{ldhL}\ >\Delta\text{sigF}\ >\Delta\text{hsdR}\) colonies were subjected to EcoRV (NEB) restriction digestion. To evaluate the 5-FOA sensitivity and uracil auxotrophy of \textit{B. smithii} ET138 \(\Delta\text{ldhL}\ >\Delta\text{sigF}\ >\Delta\text{hsdR}\) colonies were subjected to Evagold (NEB) restriction digestion. Cells were plated on TVMY medium with 30 g/L agar and the following additions: (a) 2 g/L 5-FOA and 50 mg/L uracil, (b) 2 g/L 5-FOA and no uracil, or (c) no 5-FOA and no uracil. To evaluate lactate production from \textit{B. smithii} ET138 \(\Delta\text{ldhL}\ >\Delta\text{sigF}\ >\Delta\text{ldhL}\) knock-in colonies, culture verified cells were grown overnight in TVMY medium containing 10 g/L glucose and subsequently transferred to the same medium and grown for 24 h, after which \(\alpha\)-lactate specific measurements were performed using MegaZyme K-LATE kit.

\textbf{Plasmid Construction.} Plasmids and primers used in this study are shown in Tables S2 and S3. Q5 polymerase (NEB) was used for all PCR reactions for cloning purposes. NEB T4 ligase was used for assembling the pWUR_lacZ, pWUR_Cas9nt, pWUR_Cas9nt_hr, pWUR_Cas9sp1, pWUR_Cas9sp1_hr, pWUR_Cas9sp1_hr1, and pWUR_Cas9sp1_hr2 constructs. All restriction enzymes were obtained from NEB. Purification of PCR products was performed after running them on a 0.8% agarose gel using the Zymoclean gel DNA recovery kit.

To test the \(\text{Py}_{\text{vect}}\) promoter, a DNA fragment composed of \(\text{Py}_{\text{vect}}\) and the lacZ gene was synthesized by GeneArt and inserted into pNW33n using digestion with BspHI and KpnI and subsequent ligation and cloning into \textit{E. coli} DH5\(\alpha\), creating plasmid pWUR_lacZ. The \(\text{Py}_{\text{vect}}\) sequence was used exactly as originally described\textsuperscript{47} using the sequence until the start codon of the corresponding gene in the original host.

For the construction of the basic, modular pWUR_Cas9nt construct, a synthetic gene string was synthesized by GeneArt containing the elements depicted in Figure 1B except the \(\text{Py}_{\text{vect}}\) promoter. \(\text{Py}_{\text{vect}}\) was amplified from pWUR_lacZ using primers BG6538 and BG6541. Primer BG6541 replaces the final 6 bp of \(\text{Py}_{\text{vect}}\) with an XbaI site, changing the final -1 to -6 sequence from GTAAGA to TCTAGA and keeping the total length the same as that in the original promoter. Primer BG6538 adds a BspHI site to the start of \(\text{Py}_{\text{vect}}\). The entire synthesized spCas9 module without a promoter for spCas9 was amplified using primers BG6542 and BG6543, keeping the XbaI and HindIII sites already present in the module. Subsequently, vector pNW33n was digested with BspHI and HindIII, the \(\text{Py}_{\text{vect}}\) PCR product was digested with XbaI and BspHI, and the spCas9 module PCR product was digested with XbaI and HindIII. The three elements were ligated in a three-point ligation and cloned into \textit{E. coli} TG90. The plasmid was extracted, and the correct sequence was verified by sequencing, creating plasmid pWUR_Cas9nt (Figure 2B). For transformation of this construct to \textit{B. smithii} strains, 0.1 \(\mu\)g of DNA was used rather than the standard 1 \(\mu\)g in order to more precisely determine the transformation efficiencies together with the targeting constructs described in the next section. The resulting CFUs were around 3000 and 200 per \(\mu\)g of DNA for the \(\Delta\text{ldhL}\ >\Delta\text{sigF}\) and wild-type strains, respectively. Control transformations with empty vector pNW33n yielded CFUs of 10 000 and 1800, respectively.

To insert the three different targeting spacers into pWUR_Cas9nt (which contains a nontargeting spacer), three sets of oligos were annealed to create the three spacers, after which the annealed spacers were inserted into the construct as follows. Oligo sets were BG6017 and BG6021 for spacer 1, BG6018 and BG6022 for spacer 2, and BG6019 and BG6023 for spacer 3. Each set was annealed by adding 5 \(\mu\)L of 10 mM oligo sets together with 10 \(\mu\)L of NEB buffer 2.1 and 74 \(\mu\)L of MQ water. Mixtures were heated to 94 °C for 5 min and gradually cooled to 37 °C at 0.03 °C/s using a PCR machine. Annealed oligos and plasmid pWUR_Cas9nt were digested with BspEI and BsmBI (NEB). First, BspEI digestion was performed at 37 °C for 15 min, after which BsmBI was added and the mixture was further incubated at 55 °C for 15 min. After gel purification of the digested products, ligation was performed using NEB T4 ligase, and mixtures were transformed into \textit{E. coli} TG90. All constructs were verified by sequencing, and all were correct except spacer 2, which was missing 7 nt from \(\text{Py}_{\text{vect}}\) that drives spacer expression (Figure S2). Constructs were named pWUR_Cas9sp1 to pWUR_Cas9sp3 according to their corresponding spacer. For transformation of this construct into \textit{B. smithii} strains, 0.1 \(\mu\)g of DNA was used rather than the standard 1 \(\mu\)g in order to more precisely determine the transformation efficiencies. The resulting CFUs were 700–3300 and 9–300 per \(\mu\)g of DNA for the \(\Delta\text{ldhL}\ >\Delta\text{sigF}\) and wild-type strains, respectively. Control transformations with empty vector pNW33n yielded CFUs of 10 000 and 1800, respectively.

To insert the \(\text{pyrF}\) flanks into the pWUR_Cas9nt and pWUR_Cas9sp1 constructs, the already fused \(\text{pyrF}\) flanks were amplified from a previous plasmid in which the flanks were added as follows: flanks were cloned from genomic DNA of ET 138 using primers BG 5798, BG5799 (upstream, 958 bp) and BG580, BG5801 (downstream, 979 bp), introducing Sall and XbaI restriction sites. The flanks were fused in an overlap extension PCR using primers BG5798 and BG5801, making use of the complementary overhangs in primers BG5799 and BG5800. Subsequently, the flanks and pNW33n were digested with Sall and XbaI, ligated, and transformed into \textit{E. coli} DH5\(\alpha\). To amplify the flanks for insertion into spCas9-editing plasmids, primers BG6850 and BG6849 were used, which both introduce a BspHI site. The pWUR_Cas9nt and pWUR_Cas9sp1 plasmids and the amplified \(\text{pyrF}\) flanks were digested with BspHI, followed by alkaline phosphatase treatment of the vectors (Thermo Scientific), ligated, and
transferred into E. coli TG90. Since only one restriction site was used, the flanks could have been inserted in both orientations. For both constructs, multiple colonies were verified by sequencing, and for all constructs, the same flank orientation was selected and used for future experiments, namely, the downstream flank on the P$_{syn}$ side. The resulting plasmids were named pWUR_Cas9nt_hr and pWUR_Cas9sp1_hr. Transformation of these constructs into B. smithii ΔldhL ΔsigF using 0.1 μg of DNA like that for the nonflanked versions did not yield any colonies, most likely because there is a RM recognition site present in the flanking regions (data not shown). Transformations performed using 5–8 μg of DNA resulted in CFUs of around 10 per mL screw-capped tubes containing 0.5 g of zirconium beads, 30 μL of 0.5 M Tris-HCl, pH 8.0 and kept on ice. All samples were divided into two 2 mL cultures were centrifuged at 4°C and 10 000 rpm for 5 min. 400 μL of the water phase from each tube was transferred to a new tube and mixed with 300 μL of the lysis buffer from the high pure RNA isolation kit (Eppendorf). For synthesis of the first-strand cDNA, 2 μg of RNA and 200 ng of random primers were used. After cDNA synthesis, the products were used as a template for PCR using spCas9-specific forward and reverse primers BG6237 and BG6232, resulting in a 255 bp product. Products were visualized on a 2% agarose gel that had been run for 20 min.
