INTRODUCTION

1.1 Strain rate dependency

It is today well-known and accepted that the dynamic behavior of concrete and concrete like materials are strain-rate dependent. (Grote and Park, 2001)

Compared with statically behavior, increases in strength, strain capacity and fracture energy are observed when such materials are exposed to impact loads (Lok and Zhao, 2004). The term DIF (Dynamic Increase Factor) is used to describe the relative strength enhancement.

1.2 Split Hopkinson Pressure Bar

The dynamic strength enhancement for concrete was first observed by Abrams in 1917 (Bischoff and Perry, 1991) and it has been generally accepted that concrete and concrete like materials are strain rate sensitive and the constitutive model of such materials under dynamic loading should include strain-rate effects.

Split Hopkinson pressure bar (SHPB) technique has been widely used to measure the dynamic strength enhancement at high strain-rates in the range of 10 sec\(^{-1}\) to 10\(^3\) sec\(^{-1}\).

1.3 CEB Model Code

The most comprehensive model for predicting the strain rate enhancement of concrete is presented by the CEB Model Code (Comite Euro-International du Beton - Federation Internationale de la Precontrainte, 1990)

\[
DIF = f_{cd}/f_{ct} = \left(\frac{\dot{\varepsilon}}{\varepsilon_s}\right)^{1.026\alpha} \quad \text{for } \dot{\varepsilon} \leq 30 \text{ s}^{-1} \quad (1)
\]

\[
DIF = f_{cd}/f_{ct} = \gamma \left(\frac{\dot{\varepsilon}}{\varepsilon_s}\right)^{1/3} \quad \text{for } \dot{\varepsilon} \geq 30 \text{ s}^{-1} \quad (2)
\]

The CEB DIF formulation for concrete has been accepted by most researchers as an accurate representation of the strength enhancement. The formul-
tion takes a bilinear relation between DIF and log(€) with a change in slope at strain-rate of 30 s⁻¹. (Malvar and Ross, 1998)

2 SPLIT HOPKINSON PRESSURE BAR

2.1 How the SHPB works

The principle of a SHPB device is shown in Figure 2. The axial compression impact is caused by the striker bar impinging the incident bar. When this occurs, an incident stress pulse is developed. The pulse propagates along the incident bar to the interface between the bar and the specimen. At this point, the pulse is both reflected and transmitted. The reflected wave propagates back along the incident bar and the transmitted wave attenuates in the specimen and into the transmitter bar. Both the incident and the reflected waves are measured by a strain gauge mounted on the surface at mid-length of the incident bar. Similarly, the transmitted wave is measured by a strain gauge on the surface at mid-length of the transmitter bar. (Li and Meng, 2003)

A typical output from a SHPB test is shown in Figure 5.

All three waves, ε(t), ε(t) and ε(t), are measured at the gauge locations, situated at some distance away from the interface. Therefore, an appropriate time-shifting procedure must be undertaken to transfer the strain histories from the gauge locations to the interfaces Figure 6.

To calculate the specimen stress and the dynamic increase factor, Hooke’s law is used to determine the stress of the pressure bars from the measured strain values. Based on (Linholm and Bunshah, 1971) summery of SHPB technique following strain rate, strain and stress history with respect to time, can be calculated, respectively, as
\[ \dot{\varepsilon}(t) = \frac{c_0}{L} \left[ \varepsilon_r(t) - \varepsilon_r(t_0) - \varepsilon_r(t) \right] \]  
\[ \varepsilon(t) = \frac{c_0}{L} \int_0^t \left[ \varepsilon_r(t) - \varepsilon_r(t_0) - \varepsilon_r(t) \right] dt \]  
\[ \sigma(t) = \frac{AE}{2A_s} \left[ \varepsilon_r(t) + \varepsilon_r(t) + \varepsilon_r(t) \right] \]  

2.3 Experimental program

For obtaining dynamic increase factors (DIF) for HPC in a wide range of strain rates, two different Split Hopkinson Pressure Bars has been used in this test. A 50 mm SHPB for strain rates in the range of 100 sec\(^{-1}\) to 300 sec\(^{-1}\) and a 22 mm SHPB for strain rates in the range of 600 sec\(^{-1}\) to 700 sec\(^{-1}\). Dimensions of specimen are shown in Table 1.

HPC specimens of two different strengths and 4 different mix proportions have been prepared for this test. The 50mm specimens for the 50mm SHPB were cored out of a 500 x 500 x 150mm slab. The 15 mm specimen for the 22 mm SHPB were cast in cylinders. All specimens were cured in water for 28 days at a temperature of 20°C. The mix proportions for all tested HPC are shown in Table 2 and Table 3.

* Indicates an average has been used in the plot in Figure 8.

It can be seen that the compressive strength for the 100 MPa HPC increases to 340 MPa at a strain rate of approximately 700 sec\(^{-1}\) and the compressive strength for 160 MPa HPC increases to approximately 400 MPa at a strain rate of approximately 600 sec\(^{-1}\).

Also in Figure 8 the dynamic increase factors from the constitutive CEB Model Code are presented for 100 MPa and 160 MPa, respectively. It can be observed that the CEB Model Code give matching results for the 100 MPa HPC but overestimates the dynamic strength enhancement for the 160 MPa HPC.

Figure 8. Plot of experimental results of the dynamic increase factors (DIF) compared with dynamic increase factors (DIF) derived from the CEB concrete model.
The physical mechanisms about the strength enhancement for concrete have yet not been fully understood. At least two factors, the viscoelastic character of the hardened concrete and the time-dependent micro-crack growth, may contribute to macroscopic strain rate dependent strength enhancement.

The fact that concrete and concrete like materials are hydrostatic dependent could also cause the dynamic strength enhancement seen using the SHPB device. In the SHPB test lateral confinement could wrongly be initiated from both the contact surface and the lateral inertia during the impact and because of hydrostatic dependency lead to incorrect dynamic increase factors.

As expected the dynamic strength increases with increase in strain rate. Also, as expected, the 160 MPa HPC is less sensitive to high strain rate loading than the 100 MPa HPC. A literature study revealed that no SHPB tests had earlier been conducted on concrete with strength over 100 MPa. Also revealed by that study, is that no constitutive models had been proposed for deriving the dynamic increase factor for concrete over 100 MPa. The presented results was compared with an existing constitutive model for dynamic strength enhancement, and indicates that existing constitutive models only are usable for compressive strengths up to 100 MPa.

Although this programme is based on a limited number of tests only, it is recommended that new constitutive models for deriving dynamic strength enhancement for HPC are developed. In addition extra SHPB tests and special setup will be required to determine the dynamic tensile strength of HPC.

5 CONCLUSION

An experimental investigation of the dynamic behaviour of High Performance Concretes (HPC) has been conducted using two different Split Hopkinson Pressure Bar devices. The statically compressive strengths of the tested HPC are 100 MPa and 160 MPa, respectively. The specimen has been tested at strain rates in the range of 100 sec\(^{-1}\) to 700 sec\(^{-1}\).

The dynamic increase factor (DIF) for compressive strength due to strain rate effects is between 1.84 and 3.40 for 100 MPa HPC, and between 1.17 and 2.47 for 160 MPa HPC, respectively.

Comparing the results with the constitutive CEB Model Code shows accordance for the 100 MPa HPC but only accordance in a very slight extent for the 160 MPa HPC.

It is recommended that new and more accurate constitutive models for deriving dynamic strength enhancement for HPC are developed.

The following symbols and equations are used in this paper:

\[ A = \text{cross-section area of pressure bar} \]
\[ A_s = \text{cross-section area of specimen} \]
\[ D = \text{specimen diameter} \]
\[ E = \text{Young’s modulus of pressure bar} \]
\[ L = \text{length of specimen} \]
\[ c_0 = \text{wave velocity in pressure bar} \]
\[ f_{cd} = \text{dynamic compressive strength} \]
\[ f_{cs} = \text{static compressive strength} \]
\[ f_{ts} = \text{static tensile strength} \]
\[ f_{cd}/f_{cs} = \text{compressive DIF} \]
\[ f_{td}/f_{ts} = \text{tensile DIF} \]
\[ f'_{co} = 10 \text{ MPa} \]
\[ t = \text{time} \]
\[ \varepsilon = \text{strain} \]
\[ \varepsilon/\dot{n} = \text{strain rate (dynamic)} \]
\[ \varepsilon_s = \text{strain rate (static)} \]
\[ \log \gamma = 6.156 \alpha – 2 \]
\[ \alpha = 1/(5+9 f_{cs}/f'_{co}) \]
