ABSTRACT: Studies of vertical profiles of phytoplankton in the field combined with laboratory experiments demonstrated that reduction in phytoplankton concentrations in the near-bottom water layer, 5 to 10 cm in thickness on calm days, may play a significant role for the filter-feeding polychaete *Nereis diversicolor* in realizing its grazing capacity (estimated at 13.8 m³ m⁻² d⁻¹ in the shallow bay of Kertinge Nor, Denmark, in July 1994). Field-growth experiments were performed with worms transferred to U-shaped glass tubes placed at different heights (0, 4, 10 and 20 cm) above the seafloor. A considerably reduced specific growth rate of worms at the seafloor (0.2 ± 1.1 % d⁻¹), compared to worms elevated just 10 cm above the sediment surface (2.5 ± 0.8 % d⁻¹), indicates that extremely meagre food conditions may be prevailing at the bottom. Experimental laboratory data on the development of vertical algal cell profiles were compared with predicted values obtained by means of a simple diffusion model.

KEY WORDS: Grazing impact - Vertical phytoplankton profiles - Ingestion layer - Specific growth rate

INTRODUCTION

Benthic filter-feeding macro-invertebrates may have a pronounced grazing impact on phytoplankton biomass in many shallow marine areas. A number of studies have shown that densities of filter-feeding bivalves (Jørgensen 1980, Cloern 1982, Officer et al. 1982, Nichols 1983, Loo & Rosenberg 1989), ascidians (Petersen & Riisgård 1992) and different species of polychaetes (e.g. Davies et al. 1989, Riisgård 1994) based on known filtration rates have the potential for filtering the total volume of water of their environment several times per day. If the water column is well mixed the filter-feeding bottom fauna may thus theoretically be able to control the pelagic primary production in many shallow and coastal waters.

During recent years a number of studies have been carried out to address questions dealing with the facultative filter-feeding polychaete *Nereis diversicolor* (Riisgård 1991, Riisgård et al. 1992, Vedel & Riisgård 1993, Vedel et al. 1994, Nielsen et al. 1995; for an overview of recent findings see Riisgård 1994). *N. diversicolor* may meet its food requirements on a pure diet of phytoplankton and may be an undervalued key organism in the control of phytoplankton in many shallow brackish water areas. Because *N. diversicolor* may utilize different feeding methods depending on season, phytoplankton biomass and local conditions, it is important to determine to what extent this polychaete filter-feeds. Such data were obtained by Vedel et al. (1994) using a refined monitoring system to obtain continuous, long term field measurements of the filter-feeding activity of this worm. They found that filter-feeding was 'triggered' by the presence of phytoplankton in the water, and that *N. diversicolor* utilized filter-feeding 50 to 100 % of the time during the summer period. The grazing impact of *N. diversicolor* was potentially 5.6 m³ m⁻² d⁻¹ in May, representing a volume 11 to 55 times greater than the overlying water...
column in the field. However, there was not always a clear correlation between filtration activity and chlorophyll a (chl a) measured in surface water samples. This phenomenon was assumed to be due to a restriction of the filtration activity on calm days because of the development of phytoplankton-depleted bottom water. The frequency of such incidents was suggested to have an important effect on the filter-feeding potential of N. diversicolor.

The present work describes a phytoplankton-reduced boundary layer over dense populations of Nereis diversicolor. Data was obtained through studies of vertical profiles of phytoplankton in the field combined with laboratory simulation experiments carried out with algal cells over filter-feeding N. diversicolor. Further, the presence of near-bottom reduced algal biomass was assessed through growth experiments in the field with worms placed in glass tubes at different heights above the bottom. These results show that phytoplankton-reduced boundary layers do occur and may significantly reduce the potential grazing impact and growth of N. diversicolor in nature.

MATERIALS AND METHODS

Study areas. Field experiments were conducted in 2 study areas during 1993 and 1994: the more eutrophic Odense Fjord (average water depth 0.3 m at sampling site, tidal amplitude -0.4 m, 10 to 18% S) and the less eutrophic Kertinge Nor (average water depth 0.4 m at sampling site, tidal amplitude -0.3 m, 13 to 24% S), Denmark (for localities see Fig. 1 of Vedel & Riisgård 1993). Both localities are characterized by dense populations of Nereis diversicolor.

Population investigations. Sampling during this study was carried out at a site in the southern Kertinge Nor where previous sampling had shown high densities of worms. Once a month during parts of 1993-94, 10 or 15 randomly chosen sediment core samples (92 or 143 cm²; 25 cm deep) were taken. Polychaetes that were retained by the sieve (1 mm mesh size) were individually weighed (mg wet wt) to determine population size distribution. These data were used to estimate population filtration rate using methods of Riisgård (1991) and Riisgård et al. (1992) for combining field data with laboratory data on filtration rates.

Field measurements. The importance of employing sampling protocols with realistic pumping rates and incident tube diameters (to mimic the pumping rate of filtering worms) has been emphasized by Judge et al. (1993). Therefore, the sampling tubes used in the present work had an inner diameter of 4 mm that matches the diameter of burrows of the standard Nereis diversicolor (300 to 450 mg wet wt), and the sampling volume rate did not exceed the pumping rate of the worms (i.e. <10 ml min⁻¹). The devices used for sampling water at different heights above the sediment are shown in Fig. 1. Water samples were collected simultaneously either (Fig. 1A) by siphoning the samples into plastic bottles placed on the bottom in an empty barrel, or (Fig. 1B) by using an adjustable multiple-canal peristaltic pump placed on a platform and powered by an electric generator ashore. A glass tube was fixed at the end of each sampling tube and positioned at a certain height above bottom. The water sampling rate was adjusted to equal the pumping rate of a 'standard' N. diversicolor.

Water samples for chl a measurement were immediately filtered (Whatman GF/C, 0.3 bar) and the filters put in 10 ml 96% ethanol and placed on ice in the dark for 24 h. The extracted chl a content was measured according to standard procedures (Arvola 1981) by measuring the absorption at 665 nm on a Perkin-Elmer model 554 spectrophotometer. Water samples (50 ml) for fluorescence measurement were gently passed through GF/C filters and the extracted chl a was determined fluorometrically (Sequoia-Turner model 450) the following day.

Laboratory experiments. The experimental aquarium (50 x 50 x 100 cm) was first filled with 20 cm of low organic sediment stripped of macrofauna, and Nereis diversicolor (individual biomass of 300 to 600 mg wet wt) was added to obtain the desirable density. In the laboratory sampling device, thin tubes (inner diameter = 1.19 mm) were employed to minimize unwanted mixing in the aquarium. The tube entrances were projecting at different heights from a vertically placed pipe.

Growth experiments. Worms (307 to 429 mg wet wt., n = 48) were placed in U-shaped, black-painted, glass tubes (4.0 mm inner diameter) and buried on the study location in Kertinge Nor with the tube entrances at 0, 4 and 10 cm above the bottom. The sediment surface was covered with plastic to prevent the worms from deposit-feeding. Another 12 tubes were placed on a rack 20 cm above the bottom. Initial and final wet wts after a 14 d growth period were determined (after 24 h starvation to empty the gut and 2 min drainage on filter paper). The specific growth rate ($\mu$, d⁻¹) was calculated according to the equation: $\mu = \ln(W_t/W_0) t^{-1}$, where $W_t$ and $W_0$ are the individual body wet wt of polychaetes on Days t and 0, respectively.

Growth experiments in the laboratory were performed using ad libitum feeding of shrimp meat or 2 to 3 $\times 10^4$ *Rhodomonas* sp. cells ml⁻¹. The specific growth rates were determined after 14 d.

RESULTS

Grazing impact

Population densities, biomass, and estimated population filtration capacities of *Nereis diversicolor* in Kertinge Nor during 1993 and 1994 are shown in Table 1. The grazing capacity reached a maximum level during summer due to a combination of high population biomass and high temperatures. In July 1994 the estimated population filtration rate was 13.8 m³ m⁻² d⁻¹, corresponding to a volume 35 times that of the overlying water column. In Odense Fjord the number was 2.4 m³ m⁻² d⁻¹ in June 1993 (Table 1), corresponding to 5 to 24 times that of the water column.

Vertical profiles

The laboratory experiments demonstrate the formation of a water layer with reduced phytoplankton concentrations over a population of filter-feeding *Nereis diversicolor* (Figs. 2 to 5) with no advective flow. Worm densities, measured population filtration capacities ($F_{pop}$), individual filtration rates ($F_{ind}$), and water temperatures are given in Table 2.
To examine the effect of these parameters on the thickness of the phytoplankton-reduced water layer it is convenient to introduce the concept of concentration displacement thickness, referred to as the ingestion layer. It is defined by the integral $\int_0^L [1 - C(y)/C_0] dy$, where $C_0$ and $C(y)$, respectively, are the initial and instantaneous concentrations, the latter being a function of distance $y$ above the bottom and $L$ being a

Phytoplankton densities measured as chl a on calm days in surface and near-bottom water of Odense Fjord show a reduction of about 2 times in the bottom water (Table 3). Other measurements performed in Kertinge Nor also demonstrate the presence of phytoplankton reduction in near-bottom water (Figs. 7 to 9). A pronounced phytoplankton-reduced bottom layer, corresponding to the profiles obtained in stagnant water in the laboratory experiments, is seen in Fig. 8, especially

during the first 30 min with no current. However, this was subsequently changed when the tide (Fig. 8; 90 to 180 min) caused a slow current to bring a new water mass with a higher algal content into the area (notice the new chlorophyll scale used to depict the 180 min profile). A similar situation is shown in Fig. 9A.

**Growth experiments**

The growth experiments (Table 4) suggest that reduced phytoplankton in near-bottom water is a frequently occurring phenomenon that restricts the growth of Nereis diversicolor. Specific growth rate, reflecting food supply, was about 10 times higher in worms raised 10 cm above the bottom. The maximum specific growth rates obtained in the field (2.5% d⁻¹) are considerably lower than growth rates measured on well-fed worms in the laboratory (4.9 to 5.6% d⁻¹).

**DISCUSSION**

Studies of vertical profiles of phytoplankton both in the field (Figs. 7 to 9) and in controlled laboratory experiments (Figs. 2 to 5) have demonstrated phytoplankton reduction in a near-bottom water layer, 5 to 10 cm in thickness on calm days, caused by filter-feeding Nereis diversicolor. Further, a considerably reduced growth rate of N. diversicolor at the sediment surface compared to worms elevated just 10 cm above the bottom (Table 4) indicates that extremely meagre food conditions may be prevailing at the bottom. This hitherto unnoticed phenomenon may also explain the observed unexpectedly low in situ filter-feeding activity of N. diversicolor (cf. Vedel et al. 1994).

The reduction of phytoplankton in the near-bottom water layer is a natural consequence of the activity of benthic filter-feeders. This is readily demonstrated in well-controlled laboratory experiments, involving no...
global advection currents. Here the transient evolution of a concentration boundary layer can be modelled as a simple diffusion process, starting from an initially uniform algal concentration and subjected to a flux boundary condition at the bottom and an effective diffusivity in the agitated water. At the bottom, inhalant water, being filtered and subsequently exhaled, represents a net drain of phytoplankton that can be expressed as a flux depending on the actual concentration at the bottom. In addition, inhalant and exhalant currents of the filter-feeders cause a mixing of the water in a region above the bottom. This mixing process involves up-currents of filtered water with a low (or zero) phytoplankton concentration, and down-currents with a higher concentration. Over time the net result is a transport of phytoplankton in the direction of decreasing concentration, a process that may be modelled in the usual way by Fick's law. The effective diffusivity in this law must be determined from experiments, and it is expected to increase with both strength of exhalant currents and population density of filter-feeders. Estimates of the magnitude of the effective diffusivity and actual filtration rates, determined from the present experiments (Figs. 2 to 5), have been used to solve the diffusion problem, assuming algal cells to be neutrally buoyant (P. S. Larsen unpubl.). The results are expressed as the increase with time of the previously defined ingestion layer. In Fig. 10, theory is compared with experimental data from the laboratory.

For the second case in Fig. 10 (the case of Fig. 5), diffusion theory gives a satisfactory prediction. For the first case (the case of Fig. 3B), however, the data fall far below predictions. One explanation for this difference is that organized convective currents still may have been present. It is more likely, however, that the population filtration capacity measured previous to the algal depletion experiment (Table 2) was not fully utilized during this experiment—possibly due to the disturbance of the sensitive filter-feeding worms. The considerable experimental uncertainty should also be noted.

More complicated and general cases of grazing impact by benthic filter-feeders involve turbulent and/or tidal water currents (e.g. Wildish & Kristmanson 1984, Fréchette & Bourget 1985, O'Riordan et al. 1993, Butman et al. 1994). Here, the distribution of phytoplankton concentration may, in principle, be modelled as a convection-diffusion process. The effective diffusive transport through a horizontal current leads to a boundary layer whose spatial development is dependent on: (1) the extent of populated area of bottom, (2) the upstream concentration, and (3) the mixing due to turbulence of the flow and wind-driven circulation, in addition to that induced by the filter-feeders. A suitable model for this situation remains to be developed.

As suggested above, the strength of the exhalant currents created by filter-feeding Nereis diversicolor is expected to affect the development of concentration boundary layers. The velocity of exhalant currents (determined by the tube with inner diameter of 4 mm in the laboratory experiments) of N. diversicolor pumping 8 ml min⁻¹ (10°C, see Riisgård et al. 1992), can be estimated to be 0.7, 1.1 and 1.5 cm s⁻¹ at 5, 10 and 15°C, respectively. Despite the considerable change of temperature in the present experiments, the results do not show a clear effect of it on the thickness of the mixing layer or the deduced effective diffusivity used in the modelling shown in Fig. 10.
