Abstract
A new approach to negative feedback is proposed and applied to active mixer cells based on Gilbert multipliers. The feedback can be exploited in several ways, and different configurations are derived. A dual-loop topology provides a solution for inductor-less broad-band receiver stages. The nature of the dual loop ensures controlled gain and input matching, and a first-order linearity analysis is presented. A single-loop narrow-band topology is derived from more traditional implementations; main characteristics are examined thoroughly, with specific respect to input matching, noise and stability issues.

1. Introduction
Traditional active mixers based on the Gilbert cell [1], like the one depicted in Figure 1(a), are ubiquitous in modern RF architectures. The design of such cells is carried out under the general assumption that the linearity of the block is intimately related to the linearity of the transconductor (M1 in the figure). To improve linearity performances, several solutions have been devised, most of which are based on a combination of the following methods [2]: feedback, feedforward, predistortion and piecewise approximation. Feedback-based solutions have been traditionally relegated to low-frequency applications, because of the intrinsic bandwidth reduction associated with the feedback. As more advanced technologies become available, bandwidth limitations become less and less critical. To fully exploit the capabilities of negative feedback, it would be beneficial to embrace the complete cell (transconductor and switching pair) into the feedback loop, rather than simply closing the loop locally by means of source degeneration as illustrated in Figure 1(b). A solution is sketched in Section 2, and is further developed in Section 3, where a complete dual-loop wide-band receiver front-end is proposed. In the design of a receiver chain, linearity and noise are closely related; a narrow-band solution is proposed in Section 4, where the same principle described in the following is applied in order to improve noise performances. Conclusions are drawn in Section 5.

2. Basic concept
The cell in Figure 1(c) is perfectly equivalent to the one in Figure 1(a) with respect to the downconverted signal. The node $v_m$, however, has some interesting properties at high frequency. We model the differential pair ($M_2 - M_3$) as a couple of switches, controlled by a time-variant periodic function at frequency $f_{LO}$, like in Figure 1(d), indicating the function as $m_{LO}(t)$. When passives are connected like in Figure 1(e), the computation of the output voltages is more involved, and we will develop it with the aid of Figure 2. We can easily show that the following relations hold:

$$v_h = \frac{i_n R \left(1 + \frac{sCR}{1 + sCR}\right)}{1 + \frac{sCR}{1 + sCR}}; \quad v_t = \frac{i_n R \left(1 - m_{LO}\right)}{2 \left(1 + \frac{sCR}{1 + sCR}\right)}$$  \hspace{0.5cm} (1)

$$v_m = \frac{i_n R}{2}$$  \hspace{0.5cm} (2)

The application to the structure in Figure 1(c) is straightforward, due to the symmetry properties:

$$v_{RF} = -i_{RF} \frac{1 + m_{LO} \frac{v_h}{i_m} - i_{RF} \frac{1 - m_{LO} \frac{v_t}{i_m}}{2} - \left( -i_{RF} \frac{1 + m_{LO} \frac{v_t}{i_m} - i_{RF} \frac{1 - m_{LO} \frac{v_h}{i_m}}{2} \right)}{-i_{RF} \frac{1 + m_{LO} \frac{v_h}{i_m} - i_{RF} \frac{1 - m_{LO} \frac{v_t}{i_m}}{2} \right)}$$  \hspace{0.5cm} (3)

$$v_m = -i_{RF} \frac{1 + m_{LO} \frac{R}{2} - i_{RF} \frac{1 - m_{LO} \frac{R}{2}}{2} \right)}{-i_{RF} \frac{R}{2}$$  \hspace{0.5cm} (4)

As we can see in (3) the mixing properties in downconversion are exactly as expected. Furthermore, the input RF current is amplified at node $v_m$ without any kind of filtering or mixing. This node provides a replica of the RF input current $i_{RF}$, and it will be fed back into the loop in order to linearize the mixer’s behaviour.

3. Dual-loop wide-band implementation
Traditional single-stage broad-band LNAs for RF applications present a fundamental trade-off between input matching, noise figure and linearity. This trade-off might turn out to be simply not good enough for the particular application: several solutions have been proposed, among which feed-forward [3] and negative feedback should be mentioned. When linearity is a serious concern, negative
feedback is the preferred choice, but certain limitations occur when a single-loop feedback is implemented. As an example, we can examine the simplified schematic in Figure (3), from which it is easy to get the following result:

$$Z_{in} = \frac{R_f}{1 + A}.$$  \hspace{1cm} (5)

When we calculate the loop gain we have to impose the input-matching condition $Z_{in} = R_s$, and as a result we get:

$$G_{loop} = -\frac{A}{A + 2} \cdot G \triangleq \frac{v_{out}}{v_s} = -\frac{A}{2}.$$ \hspace{1cm} (6)

We can notice that the loop-gain magnitude $|G_{loop}|$ is even smaller than one. This solution is not very robust, because the forward gain $-A$ must be accurately controlled in order to provide the correct input matching, but no feedback can be exploited to provide such accuracy. Moreover, nonlinearities in the gain stage get no attenuation whatsoever. For all these reasons, a dual-loop solution is a more sensible choice. The proposed approach is depicted in Figure 4(a); to simplify the analysis of the stage, we consider only the behaviour at high frequency. Assuming that the impedance of low-pass capacitors $C$ is negligible, the equivalent resistance at node $v_m$ is $R_{mix} = R_2$. We can define $R_1 = \frac{R_3}{2}R_4$, and the equivalent circuit looks as in Figure 4(b): the output signal is actually $i_2$, which is the RF current that is going to be down-mixed and converted into a differential voltage signal. In this simplified picture, the circuit operates at a single frequency. From the figure we can derive a proper set of equations as follows:

$$v_a = v_s - R_S i_1; \quad (7)$$

$$v_c = R_1(i_1 + i_2); \quad v_d = R_2(i_d - i_2); \quad (8)$$

$$i_1 = g_{m1}(v_a - v_c); \quad i_2 = g_{m2}(v_b - v_d); \quad (9)$$

$$i_2 = \frac{v_a - v_d}{R_3}; \quad (10)

These equations can be modified to accommodate several parasitic effects without changing the number of relevant signals. The solution to the equations is rather bulky, but proper simplifications lead to the following results:

$$Z_{in} \approx \left(1 + \frac{R_3}{R_2} \right) \frac{R_1 R_2}{R_1 + R_2}.$$ \hspace{1cm} (11)

$$i_2 \approx \frac{v_s}{R_1 \left(1 + \frac{R_3}{Z_{in}}\right)}.$$ \hspace{1cm} (12)

The linearity analysis is very difficult to carry out, and massive simplifications must be accepted. The approach is semi-iterative and it is based on the following assumptions:

1. the non-linearities are concentrated on the trans-conductors ($M_1$ and $M_2$ in the figure). Equation (9) is modified as follows:

$$i_1 = g_{m1}(v_a - v_c) + \tilde{i}_1;$$

$$i_2 = -g_{m2}(v_b - v_d) - \tilde{i}_2, \quad (13)$$

and the new system is solved with respect to nonlinear terms $\tilde{i}_1$ and $\tilde{i}_2$.

2. Third-order non-linearities are implemented through empirical factors:

$$\tilde{i}_1 \triangleq \alpha_{31}(v_a - v_c)^3; \quad \tilde{i}_2 \triangleq \alpha_{32}(v_b - v_d)^3.$$
Figure 4: A dual-loop high-linearity stage: complete stage (a), simplified circuit (b) and broadband stage based on a shunt-series input amplifier (c). Biasing details are omitted.

Figure 5: Output 1-dB compression point for the proposed stage and the one in Figure 4(c).

3. A polynomial equation is derived: \( v_3 = g_s v_2 + \alpha_3 v_2^3 \), where \( g_s \) is the small-signal transconductance resulting from (7)-(10), and \( \alpha_3 \) is the third-order non-linear term derived from previous equations.

As an example, we can try to compare the 1-dB compression point of the proposed stage with an RX frontend based on a shunt-series LNA and a Gilbert-cell mixer, like the one showed in Figure 4(c). Shunt-series stages are based on a local degeneration on the source (provided by \( R_1 \)) and shunt feedback between gate and drain (see \( R_3 \) in the figure). In fact this is a dual-loop topology, but input-matching constraints limit the values of the degeneration resistance, and thereby the loop gain. To improve linearity, local feedback is applied to the mixer as well (by \( R_2 \)). The results are shown in Figure 5: the bias current of both LNA and mixer is swept, and the output-referred 1-dB compression point is shown. Results are based on a 0.35\( \mu \)m-process models.

4. Application to a narrow-band receiver

Narrow-band LNAs based on tuned LC-tanks are implemented in many state-of-the-art receiver chains, where specifications are highly demanding. A simplified configuration is shown in Figure 6(a); the inductive degeneration provides the correct matching [4], and a cascade stage reduces the impact of the Miller effect related to Gate-Drain capacitance at transistor \( M_1 \). The mixer is built as a direct implementation of the Gilbert multiplier.

The open loop configuration can be easily modified to provide negative feedback as shown in Figure 6(b); to simplify the structure the following assumptions are made:

1. the Miller effect is negligible, the contribution of the cascode transistor in the LNA is omitted.
2. At high frequency, the load resistors of the mixer combine in parallel with the degeneration inductor \( L_{gs} \), and we assume that the equivalent parallel resistance of the inductor is marginally affected, and we will neglect it in the following.
3. Since we are interested in the operation around resonance, we represent the load LC tank with the equivalent parallel resistance \( R_d \).
4. No parasitics are considered except the Gate-Source capacitance of transistor \( M_1 \). Switches and transconductors are ideal.
5. The quality factor of tuning inductor \( L_g \) is considered infinite.

The simplified circuit results as in Figure 6(c). We can easily determine the input impedance as follows:

\[
Z_{in} = \frac{1}{s C_{gS}^2} + s (L_g + L_o) + \frac{g_m L_s}{C_{gS}} (1 + g_m R_d). \tag{14}
\]

The result does not differ from the usual one except for the multiplying factor \( (1 + g_m R_d) \); given a certain unity-gain frequency \( \omega_T = \frac{2 g_m}{C_{gS}} \), the degeneration inductor needed for proper matching will be effectively smaller.

If the design has severe current limitations, a significant term in the total noise budget will be the current noise associated with \( M_2 \), which has a spectral density equal to \( 4 k_B T \gamma g_m^2 \) above the \( \frac{1}{2} \)-noise corner frequency. Assuming proper resonance in the input network around the operation frequency, we can calculate \( M_2 \)'s contribution.

5. Conclusions

We have devised a novel method for applying feedback techniques to traditional active mixers based on Gilbert multipliers. The approach is applied to two different topologies: a wide-band highly-reconfigurable stage exploiting dual-loop feedback, and a single-loop narrow-band frontend based on tuned LC-tank resonators. Linearity- and noise properties of the proposed circuits are analyzed and compared with more traditional solutions.
