Microchip Flow Cytometer with Integrated Polymer Optical Elements for Measurement of Scattered Light

MIC, Technical University of Denmark, Denmark

Abstract:
Flow cytometry is a very powerful method for biophysical measurement of microparticles, such as cells and bacteria. In this paper, we report an innovative microsystem, in which several different optical elements (waveguides, lenses and fiber-to-waveguide couplers) are integrated with microfluidic channels to form a complete microchip flow cytometer. All the optical elements, the microfluidic system, and the fiber-to-waveguide couplers were defined in one layer of polymer (SU-8, negative photoresist) by standard photolithography. With only one single mask procedure, all the fabrication and packaging processes can be finished in one day. Polystyrene beads were measured in the microchip flow cytometer, and three signals (Forward Scattering, Large angle Scattering and Extinction) were measured simultaneously for each bead. The average intensities of the Forward Scattered light and the incident light Extinction showed excellent linear relationship with the sizes of the beads. To our knowledge this is the first time Forward Scattered light and incident light Extinction were measured in a microsystem using integrated optics. The microsystem can be applied for analyzing different kinds of particles and cells, and can easily be integrated with other microfluidic components.

1. Introduction
Flow cytometry is widely used for analyzing chemicals, particles and cells in clinical diagnostics, biochemistry and biology. In flow cytometry cells flow through an incident light beam in a sensing region and parameters such as scattered light and fluorescence are measured to provide information on the cells (Figure 1)[1].

![Figure 1: Measurement principle of flow cytometry.](image)

Forward Scattering (FS) also called small angle scattering is measured in a very narrow scattering angle range (0.5° to the incident light) and requires therefore very precise alignment. Consequently, FS is more difficult to measure than Large angle Scattering (LS), Extinction and Fluorescence[2].

Flow cytometry can be combined with cell sorting in so-called fluorescent activated cell sorters (FACS)[3]. FACS can provide impressive efficient sorting at rates of up to 1-2 10⁹ cells/seconds, but FACS are expensive, complex and require specially trained personnel for operation and maintenance.

In the past two decades, the microfabrication technologies developed for the microelectronic industry have been applied for miniaturization of various (bio)chemical analytical instruments. Those technologies have also been utilized for miniaturizing flow cytometers[4-6] and fluorescent activated cell sorters (µFACS)[7,8]. However, nearly all biochemical microdevices using optical detection still rely on bulk optics. This is a drawback in terms of packaging because of alignment problems and shock stability. Furthermore, free-space optical elements are often difficult to miniaturize.

Integrating planar optical waveguides with the microfluidic channels may provide good solutions to these problems. Microfluidic devices with integrated silicon nitride or doped silicon dioxide waveguides have been presented in recent years[9-13]. They were fabricated using silicon micromachining techniques such as thin-film deposition and anisotropic etching with the use of two to four photolithographic mask steps. The fabrication procedures were relatively complicated and took at least a couple of weeks.

Polymers are potentially interesting materials for microfabricated devices because they are less expensive and less fragile than glass and silicon and easier to fabricate. Our lab has presented a biochemical microdevice in which the fluidic system, polymer optical waveguides, and couplers to external optical fibers are fabricated in one processing step[14]. Here we present a novel microchip flow cytometer with integrated polymer optical elements (waveguides and lenses) suitable for high performance measurement of scattered light. Both fabrication and packaging are simple and fast, resulting in devices that can be made and tested in one day.
2. Design and fabrication:

The design of the microchip flow cytometer is illustrated in the upper part of Figure 2. All the channels and optical systems were defined by standard lithography in a single layer of SU-8 (XP2075 Microchem, refractive index $n = 1.59$ at 635nm) negative photoresist. The SU-8 layer was spun on a $500\mu m$ Borofloat glass substrate ($n = 1.46$) that served as waveguide buffer layer (Figure 2 top). Air acts as cladding on each side of the $30\mu m$ wide waveguides. Finally, a PDMS lid ($n = 1.4$) was utilized to seal the flow channels and to serve as top cladding layer (Figure 2 bottom). The thickness of the SU-8 layer (about $90\mu m$) was adjusted to readily accommodate $70\mu m$ outer diameter optical fibers in the fiber couplers. The tapered groove of the coupler structure ensured self-alignment and thus very efficient coupling of light between fiber and planar waveguide. The width of the microfluidic channel was $600\mu m$ and the total dimensions of the chip were $16mm \times 14mm$.

3. Experimental Section:

Four different sizes of polystyrene beads (3, 4.5, 6, and $9\mu m$ diameter) were percolated through the chip at a flow rate of 0.1-1.0 ml/h. The beads were hydrodynamically focused in the channel by a flow of $2ml/h$ MilliQ water through each of the two sheath flow channels (Figure 2). Incident light from a HeNe laser ($633nm$) was introduced through an external optical fiber and the incident light waveguide and focused on the center of the channel by the integrated SU-8 lens (Figure 3). FS ($<5\degree$) was measured through the detection waveguide. However, this waveguide also received a small amount of direct incident light. Consequently, as a bead passes through the light beam a positive FS peak is observed first, followed by a negative Extinction (EX) peak as a result of the bead blocking the incident light (Figure 4).

LS ($90\degree$) was measured vertically through the microscope objective. Thus, for each bead 3 kinds of signals (FS, LS, EX) were measured simultaneously.

4. Results and Discussion:

The scattering signals from the measured beads were plotted in histograms of the signal intensities (peak height). The histograms of Forward Scattered light intensities are shown in Figure 5 for the four different heads sizes.

![Figure 5: Distribution of Forward Scattered light intensities for different bead sizes.](image)

During the measurements the throughput of beads was 4-25 beads/s (4-25 Hz). The widths of the signal peaks from the beads were around 10ms. The minimum distance between beads should be at least twice the signal peak width. This would limit the maximum theoretical throughput to 50-65 Hz. However, increasing the flow rates will increase the linear velocity of the beads and thereby decrease the peak width and increase the theoretical throughput. Another possibility to increase the throughput is to decrease the width of the detection window or to narrow the incident light path.

Based on the distribution of the measured signal peak heights, the means of the FS, LS, and EX values were extracted after fitting to a Gaussian distribution (Figure 5 only shows the fits for FS). Mean peak heights were then plotted as a function of bead size and fitted by linear regression (Figure 6).

The results of the linear regressions show that FS and EX have a very strong linear dependence on the particle size (regression coefficients are 0.994 and 0.991, respectively), whereas LS has slightly less linear dependence (r= 0.979). This is in agreement with the literature which states that FS and EX provide information on particle size, whereas LS provides information on surface roughness and internal structure of the particles. Here, LS only gave some information about the beads surface roughness, since all the polystyrene beads were solid. In the future, the microchip flow cytometer will be used to measure cells. These experiments will also include fluorescence labeling (FL) of cells to provide additional information on the cells. Then four different parameters (EX, FS, LS, and FL) can
be measured simultaneously for each cell in the microchip flow cytometer.
