Abstract

In this paper we present an efficient data-driven tissue deformation model. The work originates in process automation within the pig meat processing industry. In the development of tools for automating accurate cuts, knowledge on tissue deformation is of great value. The model is built from empirical data; 10 pig carcasses are subjected to deformation from a controlled source imitating the cutting tool. The tissue deformation is quantified by means of steel markers inserted into the carcass as a three-dimensional lattice. For each subject marker displacements are monitored through two consecutive computed tomography images – before and after deformation; tracing corresponding markers provides accurate information on the tissue deformation. To enable modelling of the observed deformations, the displacements are parameterised applying methods from point-based registration. The parameterisation is based on compactly supported radial basis functions, expressing the displacements by parameter sets comparable between subjects. For modelling the tissue deformation, principal component analysis is applied, treating each of the parameter sets as an observation. Using leave-one-out cross-validation, marker displacements are estimated in all subjects from the mean parameters. This yields an absolute error with mean 1.41 mm. The observed lateral movement of the loin muscle is analysed in relation to the principal modes, and the results are compared to manual measurements of carcass composition. We find an association between the first principal mode and the lateral movement. Furthermore, there is a link between this and the ratio of meat-fat quantity – a potentially very useful finding since existing tools for carcass grading and sorting measure equivalent quantities.

1. Introduction

In the meat industry there is increasing interest in developing tools for process automation. The traditional manual slaughtering procedures give rise to a labour-intensive working environment with physically demanding tasks and repetitive work performed under pressure. The goals of efficient automated processing include safer and faster production, better hygiene, more uniform quality of the end products, and in the end, better returns for abattoirs.

Existing automation tools in pig meat production include systems for classifying and sorting carcasses, as well as robotics for evisceration, carcass cutting, boning and trimming various parts. Technologies currently used here are mostly computer vision and ultrasonics [7, 9]. An upcoming technology in automation is the use of computed tomography (CT) to achieve detailed information on the raw materials. Both in measuring general tendencies of populations, but also for on-line use in the abattoirs.

One hurdle in the development of the robotics is to handle the large biological variation present in the raw material – automatically adapting the processing to each individual subject. Within this area, an important topic is prediction of subject behaviour during handling, e.g. fixing a piece of meat for cutting can induce tissue deformations making it difficult for the machine to perform accurate cuts.

In this paper we use CT images as guidance in the development of a tool for processing pig backs to produce bacon with a given fat-layer thickness; homogeneous products from inhomogeneous raw materials. Figure 1 shows a 3-dimensional model of a pig back created from a CT image. Figure 1(a) shows the model with a distinction between the meat and the rind (facing down). Figure 1(b) shows the model after a ‘virtual cut’ has been performed, leaving only the rind. From the model we can see that the transition between fat and meat is far from smooth, thus a robot trimming the fat layer must be able to adjust to the shape of each individual subject [1].

Initial stages of the development process have identified the need for information on the tissue deformations caused by handling the pig back. Pressure from the knives trimming the rind tends to cause lateral movement in the loin muscle, making it difficult to perform accurate cuts. We study a simplified version of this by applying pressure from a single bolt on the skin surface and examining the induced tissue deformation in the area around the loin.
Figure 1. 3D model of a pig back created from a CT scan. (a) Model distinguishing between the loin and streaky (top) and the rind (bottom). (b) ‘Virtual cut’ showing only the rind layer; the variation of the contours in the transition between meat and rind is evident.

Tissue deformation modelling is a widespread area of research within medical imaging, e.g. haptic interfaces with realistic feedback used in simulation tools for surgical training.

A widely used approach for implementing these models is the use of finite element methods with material properties determined from both in vivo and ex vivo experiments. A thorough overview of such continuum-mechanical models is presented by Famaey and Sloten in [4] in relation to applications in virtual surgery and surgical robotics. Another approach is the use of basis functions to model tissue deformations – a method related to image registration, forming the warp function as sums of smooth basis functions. Wachowiak et al. [10] describe an application to needle insertion simulation in prostate brachytherapy using radial basis functions with compact support.

Recently, Mosbech et al. [8] presented a method for accurate quantification of soft tissue deformation, they proposed a technique based on CT images of soft tissue with inserted steel markers. We use this method in our data-driven analysis of tissue deformation. Markers are placed inside the tissue and the tissue is subjected to deformation. The resulting marker movements are monitored using CT imaging, enabling automatic generation of accurate landmarks. The observed landmark displacements are then used to analyse the induced soft tissue deformation.

2. Data Acquisition

For the experiments we used 10 pig backs of varying size and composition (quantity of fat and meat). In each subject a number of steel markers were inserted with a syringe through the skin. The steel markers had a diameter of 0.5 mm. The insertions were performed such that the markers resembled a 3-dimensional lattice of approximately 180 mm × 40 mm × 70 mm. The number of inserted markers varied between 113 and 140 because of different subject sizes.

We mounted the bolt for inducing the tissue deformation on a nylon plate. Each pig back subject was put on the plate with the rind-side facing down. The subject was aligned, such that the bolt was positioned on the skin in the middle of the lattice of injected markers. On the meat-side of the subject we placed a soft cushion to prevent the subject from being dislodged unintentionally. For each subject we did two consecutive CT scans; one without any deformation induced by the bolt, and one pressing the bolt 20 mm against the skin surface.

The images were acquired with approximately isotropic voxels; 0.9375 mm × 0.9375 mm, with a slice thickness of 1 mm. Figure 2 shows examples of the image data.

3. Methods

Compared to the surrounding soft tissue, the steel markers lead to very high intensities in the CT images. The positions can therefore be extracted accurately by intensity thresholding.

For each subject this gives two point sets of size $n$ in $d = 3$ dimensions; $\mathcal{P}$ and $\mathcal{Q} \in \mathbb{R}^{n \times d}$, holding marker positions retrieved from the two images with and without deformation, respectively.

To automatically achieve point-correspondences within each subject, we apply the Hungarian Algorithm [6], matching point pairs in the two sets by minimising the sum of the Euclidean distances.

As the 10 resulting sets of pairs differ in both size and marker positions, no point-correspondences can be established between subjects. Thus the tissue deformations contained in the marker displacements are difficult to compare across subjects. To facilitate comparison we parameterise the marker displacements, bringing them into a common
reference frame.

The parameterisation can be regarded as a task from point-based registration; determining a geometrical transformation aligning point-pairs by estimating displacements. We formulate this alignment of two corresponding points \( p_i \in P \) and \( q_i \in Q \) as a function \( \phi \) of parameters \( x \in \mathbb{R}^{d \times n_k} \)

\[
\phi(p_i, x) = p_i + u(p_i, x)  
\]  
(1)

modelling the displacements by the parametric transformation \( u : (\mathbb{R}^d, \mathbb{R}^{d \times n_k}) \rightarrow \mathbb{R}^d \).

The transformation is composed of a sum of basis functions \( \psi \) defined on a set of knot points \( C \in \mathbb{R}^{n_k \times d} \) all within the spatial range of \( P \). For a single point the displacement in one direction is the sum of \( n_k \) basis functions

\[
u(p_i, x) = \sum_{j=1}^{n_k} x_j \psi(r_j),  
\]  
(2)

where \( r_j = \|p_i - c_j\| \); the Euclidean distance between the point \( p_i \in P \) and knot \( c_j \in C \).

As basis functions we use a certain type of radial basis function with compact support \( \psi_{d,k} \in C^{2k}(\mathbb{R}) \) as introduced by Wendland [11]. In [5] Fornefett et al. describe an application of these functions to model deformations in relation to registration of medical images. For dimension \( d = 3 \) and smoothness \( k = 2 \) the Wendland-basis function is formulated as

\[
\psi_{3,2} = (1 - r)^6_+ (35r^2 + 18r + 3).  
\]  
(3)

In this univariate polynomial, the compact support is controlled by \( (1 - r)^6_+ = (1 - r)^6 \) for \( 0 \leq r \leq 1 \) and 0 for \( r > 1 \). A parameter \( a > 0 \) can be applied for scaling this locality; \( \psi(r) \equiv \psi(r/a) \). That is, the global effect of \( \psi \) increases with \( a \), as all points within distance \( a \) from a particular knot are affected.

The optimal vector of parameters \( x \in \mathbb{R}^{n_k} \) to represent one direction of the tissue deformation contained in all pairs in \( P \) and \( Q \) for one subject is determined by minimising a sum of \( n \) squared pair-wise Euclidean distances between observations and estimates

\[
\argmin_{x} \sum_{i=1}^{n} \|q_i - \phi(p_i, x)\|^2.  
\]  
(4)

With (1) and (2) we can construct the estimates as a linear system of equations

\[
\hat{q} = p + Ax,  
\]  
(5)

where \( p, \hat{q} \in \mathbb{R}^n \) and \( A \) is an \( n \times n_k \) matrix of basis function values \( \{A\}_{ij} = \psi_{d,k}((|p_i - c_j|)) \). The system can be expanded to estimate displacements in all three dimensions;

\[
\hat{q} = p + \begin{bmatrix} A & 0 & 0 \\ 0 & A & 0 \\ 0 & 0 & A \end{bmatrix} x,  
\]  
(6)

with \( p, \hat{q} \in \mathbb{R}^{d \times n} \) and parameters \( x \in \mathbb{R}^{d \times n_k} \). This can be solved using standard optimisation techniques, e.g. by
Figure 3. A mesh of points with 5 mm spacing deformed under the estimated parameters. The mesh is superimposed on two planes of the CT image. As the deformation is three-dimensional, part of the grid is disappears into the image slice from this perspective.

minimising the cost function equivalent to (4) w.r.t. \( x \)

\[
f = \frac{1}{2} (q - (p + A_0 x))^T (q - (p + A_0 x))
\]  

where \( A_0 \) is the block diagonal matrix of (6).

This parametric representation of the observed marker displacements enables estimation of the tissue deformation between the markers. Applying the same basis function parameters and set of knot points, the \( A \) matrix of (5) is computed with respect to these new points of interest (e.g. all voxel positions). The parameters can then be plugged into (6) for computing the displacements. Figure 3 shows an example.

4. Analysis

As mentioned earlier, the \( N = 10 \) tissue deformations are comparable by means of their parameter vectors, when the same parameterisation has been applied on all subjects. This implies using the same values of \( a, d \) and \( k \), but also a common knot set-up \( C \). To handle this knot-set, a steel marker placed on the tip of the pressure bolt is used as origin for consistent positioning of the knot-grid on all subjects.

We analyse the variability of the estimated parameters by applying principal component analysis (PCA), building a general model with methods from statistical shape modelling [3].

Regarding each of the estimated parameter vectors as an observation of a random variable, we estimate the mean

\[
x = \frac{1}{N} \sum_{s=1}^{N} x_s
\]

and calculate the covariance matrix of the parameters with the mean subtracted

\[
\Sigma = \frac{1}{N-1} \sum_{s=1}^{N} (x_s - \bar{x})(x_s - \bar{x})^T
\]

The eigenvectors and eigenvalues of \( \Sigma \) are then estimated, and the eigenvalues are sorted non-increasing; \( \lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_{d-n_k} \). The corresponding eigenvectors are gathered in a matrix forming an orthonormal basis; \( P = [P_1 P_2 \cdots P_{d-n_k}] \). These vectors are the principal modes forming the model for approximating a parameter vector; adding the mean and a linear combination of modes

\[
x = \bar{x} + P' b',
\]

where \( P' \) is a subset of \( P \) containing the \( l \) first modes, and \( b' \in \mathbb{R}^l \) is the model parameters.

Using leave-one-out cross-validation, \( N \) models are estimated – each from \( N - 1 \) observations. We assess the generality of the model by considering the simplest model consisting of the mean deformation parameters only. Instead of applying the transformations on regular grids as shown in figure 3, we apply them to the set of marker positions corresponding to the parameter set left out in building the model. In this way we can estimate the prediction error of the model, comparing estimated and observed displacements. This yields an absolute error of \( 1.41 \pm 0.87 \text{ mm} \) comparable to the voxel size of the images.

To examine the effects of the modes in detail, the zero-mean parameter vector is projected onto the full set of modes

\[
b = P^T (x - \bar{x}),
\]

the deformation parameters are then reconstructed using only the model parameters and modes of interest as in (10). We take an approach slightly different from the model formulated in (10) and (11). No cross-validation is applied, and the mean is disregarded, as its effect on the deformations is common for all observations. In the PCA model the amount of the data set’s variation represented by the \( i \)th mode is proportional to the relative size of the \( i \)th eigenvalue. The graph in figure 4 relates the number of modes in the model to the percentage of variance explained. We show only the first nine modes – explaining the full variance – as the model is built from 10 observations.

The three first modes cover approximately two-thirds of the total variance. With the approach described above, we examine the effect on the tissue deformation of each of the modes individually. Figure 5 shows an example of the results; using the reconstructed deformation parameters, we calculate displacements for a grid of points – covering the range of the knots and markers – and visualise them as arrows superimposed on the corresponding image slice.

For the first three modes, the estimated displacements show no general tendencies in the streaky-part of the backs.
Figure 4. Graph showing the percentage of variance explained by
the principal modes. The nine first modes are used to explain all
of the variance, as the model is built from 10 observations.

(rightmost on the example in figure 5). As this part ex-
hibits a highly variable anatomical structure throughout the
10 subjects, it is difficult for the model to generalise these
deformations.

Regarding the estimated point displacements in the loin
muscle, the first mode – explaining 37 % of the total vari-
ance – shows a relation to the degree of lateral movement
for all subjects. The movement appears to be most pro-
found in the tissue around the tip of the pressure bolt, but
on some subjects it propagates even further into the muscle.
As mentioned in the introduction, this lateral movement is
of particular interest in the development of automated tools
for precise rind trimming. The movement complicates the
process of producing a product with a given fat layer thick-
ness.

We focus the analysis on this first principal mode and ex-
amine the resulting displacements of points within the loin
muscle and in the rind layer beneath it. The points are se-
lected by means of manual segmentations of the loin mus-
cle.

Existing carcass grading systems are capable of perform-
ning measurements of the fat and loin muscle thickness [2],
so it is sensible to use these two measurements to charac-
terise the carcass composition of the subjects – that is, for
each subject we also perform a manual segmentation to as-
sess the mean fat layer thickness. Figure 6 relates the esti-
mated lateral movements to the ratio between loin size and
mean fat layer thickness. For subjects 2 and 9 – with no-
table positive displacement means – the loin muscle is not
moving to the right, since the left-directed deformation con-
tained in the mean is disregarded in the analysis. From the
figure we see, that the lateral movement differs clearly from
the rest on the most lean and fat subjects. This indicates the
possibility of sorting the pig backs by means of the loin-fat
ratio and discriminating the processing – e.g. by applying
uneven pressure on the meat side to compensate for the lat-
eral movement of the muscle.

Figure 5. The effect of the mean and each of the three first prin-
cipal modes. (a) The displacements are illustrated on a single slice
zoomed to a region around the pressure bolt containing parts of
the streaky (right) and loin muscle (left). (b) Four slices; the dis-
placements are estimated for a grid of points and shown as lines
superimposed on the image (from top to bottom; mean, modes 1,
2 and 3). For illustrative purposes the lines corresponding to the
three single modes have been magnified by a factor of five.
Figure 6. Analysing the first principal mode regarding displacements estimated for points within the loin muscle and in the fat layer beneath it. (a) Plot relating lateral movement (x-axis) and ratio between the manual measurements of loin size and mean fat layer thickness (y-axis). (b) Illustrating three different carcass compositions resulting in different lateral loin muscle movements. From top to bottom the slices are subjects 4, 1 and 9.

5. Conclusion

This paper described an efficient method for data-driven modelling deformation of soft tissue. The model is based on three-dimensional computed tomography images of 10 pig carcasses subjected to deformation. The tissue deformation is accurately quantified by steel markers inserted into the carcass. The observed displacements from each subject are transformed into a common reference frame with a parametric representation of radial basis functions with compact support.

The derived parameters are compared using principal component analysis, forming a tissue deformation model. The generalisation of the model is assessed by estimating marker displacements from the mean parameters using leave-one-out cross-validation by subject. Across all subjects the model achieves an absolute error of 1.41 ± 0.87 mm. The first principal mode of the model covers 37% of the total variance in the data. This mode is associated with the lateral movement of the loin muscle. The magnitude of this movement is compared with measurements of carcass composition; the ratio between loin size and mean fat layer thickness. The comparison shows a link; lean carcasses exhibit a higher degree of lateral loin muscle movement compared to more fatty carcasses.

In pig meat production, the presented method can provide valuable knowledge in relation to developing tools for automated processing. Our analyses are of particular interest in relation to trimming the rind of pig backs producing a product with a given fat layer thickness.
