We study spin-polarized transient transport in a quantum dot coupled to two ferromagnetic leads subjected to a rectangular bias voltage pulse. Time-dependent spin-resolved currents, occupations, spin accumulation, and tunneling magnetoresistance (TMR) are calculated using both nonequilibrium Green function and master equation techniques. Both parallel- and antiparallel-lead magnetization alignments are analyzed. Our main findings are a dynamical spin accumulation that changes sign in time, a short-lived pulse of spin polarized current in the emitter lead (but not in the collector lead), and a dynamical TMR that develops negative values in the transient regime. We also observe that the intradot Coulomb interaction can enhance even further the negative values of the TMR.

I. INTRODUCTION

A variety of new effects and novel devices have been reported during recent years in the context of the emerging field of spintronics.1–4 One of the most challenging milestones in this context is the development of a quantum computer, which would represent a great breakthrough in the processing time of certain mathematical and physical problems.5 In particular, the electron spin in quantum dots has been proposed as a building block for the implementation of quantum bits (qubits) for quantum computation.6,7 An important recent development is the possibility to coherently control electron states and electron spin in quantum dot systems with a precision up to a single electron, thus demonstrating the feasibility of qubit implementation in a solid-state system.8–13 Specifically, these experimental realizations use high-speed voltage pulses to tune the system levels in a coherent cycle for electronic manipulation. ac-driven quantum dot systems and double-barrier structures have also been studied in the context of quantum pumps,14–18 superlattices,19 Kondo effect,20–23 and spin-polarized transport.24,25 In addition to this, time-dependent transport has received growing attention in a variety of mesoscopic systems that encompass, to mention but a few, molecular electronics,26,27 dissipative-driven mesoscopic ring,28 noisy qubits,29 and dynamical Franz-Keldysh effect.30

In the context of spintronics a system of particular interest is composed of a quantum dot or a metallic island coupled via tunnel barriers to two ferromagnetic leads (FM-QD-FM). For example, in the nonequilibrium regime the following effects have been discussed: a spin-split Kondo resonance,31,32 a spin-current diode effect,33 zero-bias anomaly,34 tunnel magnetoresistance (TMR) oscillations,35 negative TMR,36 spin accumulation,37 and so on. In spite of all this activity, to the best of our knowledge, only very little work has been done on spin-polarized transport driven by ac-bias voltages.24,25 Here we study transient spin-resolved currents, occupations, and TMR generated by a voltage pulse applied in one of the ferromagnetic leads. We use two complementary approaches to study the problem: the nonequilibrium Green function (NEGF) and the master equation (ME). The NEGF is used to give an exact solution in the noninteracting case, while the ME, valid in the limit \( k_BT \gg \Gamma_0 \) (\( \Gamma_0 \) is the characteristic level width), is used to demonstrate that the results obtained via the NEGF are modified only quantitatively, not qualitatively, when Coulomb interaction is accounted for in the sequential-tunneling limit. Both parallel (P) and antiparallel (AP) magnetization alignments are considered. In the P case we find a magnitude and sign modulation of the spin accumulation in the dot, while in the AP alignment only the magnitude changes. For the current we observe a spike of spin-polarized current in the emitter lead when the system operates in the P configuration. This effect gives rise to a dynamical negative-TMR just after the bias voltage is turned off.

The paper is organized as follow. In Sec. II we describe the formulation based on the NEGF and give explicit formulas for the noninteracting case. In Secs. III A–III C we present numerical results based on Sec. II, and in Sec. III D we apply the master equation technique to account Coulomb interaction effects (in the sequential tunneling limit). Finally, in Sec. IV we give some final remarks.

II. TRANSPORT FORMULATION

To describe the system of a quantum dot coupled to two ferromagnetic leads (see Fig. 1), we apply the following Hamiltonian

\[
H = \sum_{k,\sigma} \varepsilon_k c_{k\sigma}^\dagger c_{k\sigma} + \frac{1}{\sigma} \sum_{\sigma} \varepsilon_{\sigma}(t) d_{\sigma}^\dagger d_{\sigma} + \sum_{k,\sigma} \left(V_{k,\sigma} c_{k\sigma}^\dagger d_{\sigma} + V_{k,\sigma}^* d_{\sigma}^\dagger c_{k\sigma} + U n_\sigma n_{\bar{\sigma}} \right),
\]

where \( \varepsilon_{k\sigma}(t) \) is a time-dependent free-electron energy with
wave vector $k$ and spin $\sigma$ in lead $\eta (\eta=L, R)$. This energy can also be written as $E_{k\sigma}(t) = E^0_{k\sigma}(t) + \Delta_{\sigma}(t)$, with $E^0_{k\sigma}(t)$ being the time-independent energy and $\Delta_{\sigma}(t)$ gives the time evolution of the external bias. The energy $E_{d}(t)$ is the time-dependent spin-degenerate dot level, which can also be written as $E^0_{d}(t) + \Delta_{d}(t)$, where $E^0_{d}$ is the time-independent level and $\Delta_{d}(t)$ follows the bias voltage. It should be noted that in a quantitative theory one should consider a level shift $\Delta_{d,\eta}$ which depends on the level occupation, via some suitable self-consistent procedure. We shall address this issue in our future work, but for the present purpose the simple model suffices.

The operator $c^\dagger_{k\sigma \eta}(\epsilon^0_{k\sigma \eta})$ is an annihilation (creation) operator for a single-particle momentum state $k$ and spin $\sigma$ in lead $\eta (\eta=L, R)$, and $d_{\sigma} (d^\dagger_{\sigma})$ is an annihilation (creation) operator for the single-particle dot’s state $e_{d}$. The matrix element $V_{k\sigma \eta \sigma'}$, couples the leads with the dot, and we assume that the tunneling process is spin independent. Finally, the $U$ term describes the Coulomb repulsion in the dot, with $n_{\sigma} = d_{\sigma}^\dagger d_{\sigma}$.

In order to calculate the current we use the definition $I_{\eta}^{\sigma}(t) = e(\epsilon_{d})\langle N_{\eta}^{\sigma}(t) \rangle$, where $e$ is the electron charge ($e>0$) and $N_{\eta}^{\sigma} = \sum_{k\sigma} c_{k\sigma \eta}^\dagger c_{k\sigma \eta}$ is the total number of electrons with spin $\sigma$ in lead $\eta$. From this definition it is straightforward to show that

$$I_{\eta}^{\sigma}(t) = 2eRe\left\{ \sum_{k} V_{k\sigma \eta \sigma} G_{\sigma, k\sigma \eta}(t, t) \right\},$$

where

$$G_{\sigma, k\sigma \eta}(t, t) = i \int_{-\infty}^{t} dt_1 V_{k\sigma \eta \sigma} \exp\left[ -i \int_{t_1}^{t} dt_2 \epsilon_{k\sigma \eta}(t_2) \right] \times \left[ G_{\sigma, k\sigma \eta}^{\tau}(t, t_1) f_{\eta}(E_{k\sigma \eta}) + G_{\sigma, k\sigma \eta}^{\tau}(t, t_1) \right],$$

(3)

with $G_{\sigma, k\sigma \eta}^{\tau}(t, t_1)$ being the retarded (lesser) Green function of the dot and $f_{\eta}(E_{k\sigma \eta})$ is the time-independent Fermi distribution function of lead $\eta$. Substituting Eq. (3) into Eq. (2) and following Ref. 38 we find

$$I_{\eta}^{\sigma}(t) = -2e \int_{-\infty}^{t} dt_1 \frac{d\epsilon}{2\pi} \text{Im}\{e^{i\epsilon(t-t_1)}\Gamma^{\eta}_{\eta}(\epsilon, t_1, t) \} \times \left[ G_{\sigma, k\sigma \eta}^{\tau}(t, t_1) f_{\eta}(\epsilon) + G_{\sigma, k\sigma \eta}^{\tau}(t, t_1) \right],$$

(4)

with $\Gamma^{\eta}_{\eta}(\epsilon, t_1, t) = 2\pi\rho_{\eta}(\epsilon)[V_{\eta}(\epsilon)\epsilon]^2 \exp[i\epsilon t]\exp[-\epsilon t]$. These results are exact, and they can in principle be used to study the intricate interplay between time dependence, coherence, and interactions. Their use, however, requires knowledge of $G^\tau$ and $G^\sigma$, which come from the solution of the nonequilibrium Dyson and Keldysh equations, respectively. For our main findings, though, it is sufficient to consider a noninteracting model, for which an exact solution can be obtained. Next, in Sec. III D, we show that our results change only slightly when Coulomb interaction is included in a master-equation-based scheme.

In the wideband limit (WBL) (Refs. 40 and 41) and for noninteracting electrons Eq. (4) can be written as

$$I_{\eta}^{\sigma}(t) = -e\Gamma^{\eta}_{\eta}\left\{ \langle n_{\sigma}(t) \rangle + \int \frac{d\epsilon}{\pi} f_{\eta}(\epsilon) \text{Im}\{A_{\sigma \eta}(\epsilon, t)\} \right\},$$

(5)

where $\langle n_{\sigma}(t) \rangle$ is the time-dependent dot’s occupation, given by

$$\langle n_{\sigma}(t) \rangle = \text{Im}\{G_{\sigma, k\sigma \eta}^{\tau}(t, t)\} = \sum_{\eta} \Gamma^{\eta}_{\eta} \int \frac{d\epsilon}{2\pi} f_{\eta}(\epsilon) |A_{\sigma \eta}(\epsilon, t)|^2,$$

(6)

and $A_{\sigma \eta}(\epsilon, t)$ is defined as

$$A_{\sigma \eta}(\epsilon, t) = \int_{-\infty}^{t} dt_1 G_{\sigma \eta}^{\tau}(t, t_1) \text{exp}\left[ i\epsilon(t-t_1) - i \int_{t_1}^{t} dt \Delta_{\sigma}(t) \right].$$

(7)

The retarded Green function in the noninteracting model is given by

$$G_{\sigma, k\sigma \eta}^{\tau}(t, t_1) = -i\theta(t-t_1) e^{-i\epsilon(k_{\sigma \eta}^0/2)(t-t_1)} \text{exp}\left[ -i \int_{t_1}^{t} d\epsilon \epsilon_{k\sigma \eta}(t) \right],$$

(8)

where $\Gamma_{\sigma}^{\eta} = \Gamma^{\eta}_{\eta} + \Gamma^{\eta}_{\eta}$. For a voltage pulse $V(t) = V_0 \theta(t) \theta(s-t)$ (see Fig. 1) and assuming that this pulse is applied on the right ferromagnetic lead, with a linear bias drop along the junction, we have $\Delta_{L}(t) = V_L - t$, $\Delta_{R}(t) = V_R(t) = V(t)$, and $\Delta_{d, L} = V_d = V(t)/2$.

With these definitions, we find $0 < t < s$ (Ref. 42),
\[
A_{\sigma\eta}(\epsilon, 0 < t < s) = \frac{e^{\epsilon(\epsilon - \epsilon_0 + V_t)} e^{(V_d - V_\eta) s}}{\epsilon - \epsilon_0 + i\Gamma_{\sigma} / 2} + \frac{1 - e^{\epsilon(\epsilon - \epsilon_0 + V_t)} e^{(V_d - V_\eta) s}}{\epsilon - \epsilon_0 + V_d - V_\eta + i\Gamma_{\sigma} / 2}.
\]

(9)

and for \( t > s \) we obtain
\[
A_{\sigma\eta}(\epsilon, t > s) = \frac{e^{\epsilon(\epsilon - \epsilon_0 + V_t)} e^{(V_d - V_\eta) s}}{\epsilon - \epsilon_0 + i\Gamma_{\sigma} / 2} + \frac{e^{\epsilon(\epsilon - \epsilon_0 + V_t)} e^{(V_d - V_\eta) s}}{\epsilon - \epsilon_0 + V_d - V_\eta + i\Gamma_{\sigma} / 2} + \frac{1 - e^{\epsilon(\epsilon - \epsilon_0 + V_t)} e^{(V_d - V_\eta) s}}{\epsilon - \epsilon_0 + i\Gamma_{\sigma} / 2}.
\]

(10)

Substituting Eqs. (9) and (10) into Eqs. (5) and (6) yields the final result for the spin-resolved occupations and currents. Numerical results are described in the next section.

III. RESULTS

A. Parameters

In our numerical calculations we assume that the voltage pulse is applied to the right electrode, so that \( \mu_{R} = -V(t) \) while \( \mu_{L} \) is kept constant equal zero. The dot’s level is taken originally (zero bias) above the chemical potentials \( \mu_{L} \) and \( \mu_{R} \). \( \epsilon_0 = 0.5 \) meV. The temperature is assumed to be \( T = 2.5 K \) (\( k_B T = 215 \) \( \mu eV \)), thus allowing a small thermally excited occupation of the dot in equilibrium. To describe the ferromagnetism of the leads we choose the tunneling rates to be \( \Gamma_{\sigma} = \Gamma_0 [1 + \epsilon_i / \Gamma_0] \) and \( \Gamma_{\sigma} = \Gamma_0 [1 - \epsilon_i / \Gamma_0] \), where \( \Gamma_0 \) is the lead-dot coupling strength and \( \epsilon_i \) gives the polarization degree of the leads. Here we assume a weak coupling with \( \Gamma_0 = 1 \) \( \mu eV \) (Refs. 44 and 45) and a polarization degree \( \rho = 0.4 \). The + and − signs in \( \Gamma_0^R \) give the parallel and antiparallel configurations, respectively. Due to the ferromagnetism of the leads (\( p \neq 0 \)), we have \( \Gamma_{\sigma}^R > \Gamma_{\sigma}^L \) and \( \Gamma_{\sigma}^R > \Gamma_{\sigma}^L \) in the parallel case and the opposite \( \Gamma_{\sigma}^R < \Gamma_{\sigma}^L \) in the antiparallel alignment. For the bias voltage we adopt \( V(t) = V_0 (t_0 - \theta(s - t)) \) where \( V_0 = 5 \) \( \mu eV \) and \( \theta = 3 \) \( ns \). The charging energy \( U \) is set equal to zero in Secs. III B and III C and equal to 3 meV in Sec. III D.

B. Spin-polarized occupations

Figure 2 shows the spin-resolved occupations \( n_1 \) and \( n_1 \) and the spin accumulation \( m = n_1 - n_1 \) as a function of time for both (a) parallel and (b) antiparallel configurations. Before the bias is turned on the level \( \epsilon_\uparrow \) is above the electrochemical potentials \( \mu_{L} \) (\( \eta = L, R \)), and the dot is only slightly occupied due to thermal excitation. When the bias is turned on at \( t = 0 \) the dot’s level is brought into resonance (\( \mu_{L} < \epsilon_\uparrow < \mu_{R} \)), thus resulting in an enhancement of \( n_\sigma \) and \( m \). In the parallel case [Fig. 2(a)] the spin-up population increases faster than the spin-down one and both attain the same stationary value around 0.5. The steeper enhancement of \( n_1 \) compared to \( n_1 \) is related to the inequality \( \Gamma_{\sigma}^L > \Gamma_{\sigma}^R \), which gives a faster response for the spin-\( \uparrow \) component.

Since \( \Gamma_{\sigma}^L = \Gamma_{\sigma}^R \) in the P case, the in- and out-tunnel rates compensate each other, thus resulting in \( n_1 = n_1 \) for asymptotic times. When the bias voltage is turned off, \( \epsilon_\uparrow \) rises above \( \mu_{L} \) and \( \mu_{R} \) and the population of the dot begins to decay, with a faster discharge for the \( \uparrow \) component. The spin accumulation reflects the dynamics of \( n_1 \) and \( n_1 \). In the range \( 0 < t < s \), \( m \) reaches a local maximum due to the faster enhancement of \( n_1 \) compared to \( n_1 \). In contrast, when the bias voltage is turned off (\( t > s \), \( m \) shows a local (negative) minimum due to the fast discharge of \( n_1 \).

In Fig. 2(b) we show the evolution of the occupations and the spin accumulation in the antiparallel alignment. We note that \( n_1 \) increases faster than \( n_1 \) as in the P case. In contrast, though, \( n_1 \) attains a higher value than \( n_1 \) in the stationary regime. This is related to the out-tunnel rates which are now inverted with respect to the parallel case: \( \Gamma_{\sigma}^L > \Gamma_{\sigma}^R \). When the bias is turned off, both \( n_1 \) and \( n_1 \) decrease due to the transient discharge. In particular the spin-up electron population discharges predominantly to the left lead while the spin-down component discharges to the right, following their corresponding majority density of states (or equivalently the majority tunnel rates). The way spins \( \uparrow \) and \( \downarrow \) charge and discharge is more clearly seen in the spin-resolved current curves described in the next section.

C. Spin-resolved currents

Figure 3 shows \( I_\uparrow \) and \( I_\downarrow \) for both leads and both ferromagnetic alignments. In the P configuration [Fig. 3(a)] the left currents \( I_\uparrow \) and \( I_\downarrow \) show a transient suppression and then attain their respective stationary values with \( I_\uparrow = I_\downarrow \). In the right lead the currents \( I_\uparrow \) and \( I_\downarrow \) increase (in modulus) up to their respective stationary values. When the bias voltage is
turned off $I^L_\sigma$ becomes negative as $I^R_\sigma$. The negative sign of both $I^L_\sigma$ and $I^R_\sigma$ means that the electrons are flowing from the dot to the leads (discharge). In particular the spin-$\downarrow$ electrons discharge much slower than the $\uparrow$ ones, due to $\Gamma_{1}^{L,R} < \Gamma_{1}^{L,R}$.

In the AP configuration [Fig. 3(b)], $I^L_\sigma$ and $I^R_\sigma$ show a suppression just after the bias voltage is turned on; then, they attain a stationary value with $I^L_\sigma=I^R_\sigma$. In the right lead the currents $I^L_\sigma$ and $I^R_\sigma$ are enhanced until they reach equal plateaus. When the bias voltage is turned off, $I^L_\sigma$ and $I^R_\sigma$ change sign (discharge of the dot) and a spike of spin-$\uparrow$ current is seen in the left lead ($I^L_{\uparrow} \gg I^L_{\downarrow}$). This reflects the preferential discharge of spin-up electrons to the left lead, according to $\Gamma_{1}^{L} < \Gamma_{1}^{R}$. No spike is seen in the parallel configuration, where spin-up electrons discharge equally to both leads. In contrast, in the AP alignment the spin-down electrons discharge preferentially to the right lead due to the inverted inequality $\Gamma_{1}^{L} > \Gamma_{1}^{R}$, while in the P case its discharge is equally to both sides ($\Gamma_{1}^{P} = \Gamma_{1}^{R}$).

**Negative TMR.** In Fig. 4 we show the total current in the left ferromagnetic lead, $I^L + I^R$, for both parallel (solid line) and antiparallel (dotted line) configurations. After the bias voltage is turned off ($t > 3$ ns) the total antiparallel current becomes greater than the parallel one, lifted by the spike of $\uparrow$ current seen in Fig. 3(b). This results in the time-dependent negative TMR seen in the inset.

The system is parallel aligned. More specifically, in the AP configuration both spin up and down discharge fast to the left and to the right leads, respectively, following their majority-spin populations (or equivalently the tunneling rates). In contrast, in the P alignment the majority populations occur for spin up in both leads ($\Gamma_{1}^{L,R} < \Gamma_{1}^{L,R}$). This turns into a fast discharge for spin-up electrons and a slow discharge for the down component. This slow spin-down discharge sustains the total current much longer than in the AP configuration, and eventually for long enough times we find $I^R_{\uparrow} \gg I^R_{\downarrow}$.

**Displacement current.** In the transient regime the left and right currents are not in general the same ($I_L \neq I_R$), due to charge accumulation and depletion in the dot. The generalized conservation law is given by the continuity equation $$I^R_\sigma = I^L_\sigma - \frac{d}{dt} n_{\sigma}$$ for spin $\sigma$, given by $I^\sigma_{\sigma} = ed(n_{\sigma}(t))/dt$. In order to check the accuracy of our numerical calculation we have verified numerically the continuity equation.

**D. Effects of the Coulomb interaction**

An exact treatment of the Coulomb interaction represents a formidable problem, and in the context of the present Hamiltonian only few results are known in equilibrium, and none in nonequilibrium, even less so under transient conditions. Nevertheless, in certain limits approximate treatments may give a good qualitative understanding of the generic behavior. One such case is the sequential-tunneling limit ($\Gamma_{0} \ll k_B T$), where the ME approach is known to work well. Here, we use the ME to estimate the effects of the Coulomb interaction in our results. The current expression is given by

$$I^\sigma_{\sigma} = e\Gamma_{\sigma} f_\sigma P_0 - (1 - f_\sigma) P_0 + \bar{f}_\sigma P_0 - (1 - \bar{f}_\sigma) P_2,$$

where $P_0 = \langle (1 - n_{\sigma}) (1 - n_{\bar{\sigma}}) \rangle$, $P_\sigma = \langle n_{\sigma} (1 - n_{\bar{\sigma}}) \rangle$, and $P_\bar{\sigma} = \langle n_{\bar{\sigma}} n_{\sigma} \rangle$ are the probabilities to have no electron, one electron with spin $\sigma$, and two electrons, respectively. The Fermi functions $f_\sigma$ and $\bar{f}_\sigma$ are evaluated at $e_{\sigma} + U$ and $e_{\bar{\sigma}} + U$, respectively. For the dot’s occupation we write
For the noninteracting case ($U=0$) the time-dependent results obtained from Eq. (11) are identical to those seen in Sec. III B and III C. For the interacting case ($U \neq 0$), we find that for $U=1$ meV the results are indistinguishable from the $U=0$ case (see Fig. 5). This is so because for small enough $U$ both channels $\varepsilon_d$ and $\varepsilon_d+U$ attain resonance for $V(t) = 5$ meV. In contrast, for $U=3$ meV the channel $\varepsilon_d+U$ remains above the emitter chemical potential when the bias voltage is applied, which turns into a suppression of the occupations and the currents. In particular in the AP configuration this suppression is stronger upon the spin-down component, seen in both occupations [panel (b)] and currents [panel (d)]. This is due to the spin imbalance $n_{1}>n_{1}$ typically present in the antiparallel alignment. This spin-polarized suppression in the AP configuration gives rise to an enhancement of the spin imbalance [see Fig. 5(b)] and to a spin-polarized current ($|I_{1}^{L,R}| > |I_{1}^{R,L}|$) in the stationary plateau.

In Fig. 6 we see the effects of $U$ on the dynamical TMR. For $U=1$ meV the TMR is basically the same as before [Fig. 4 (inset)]. For $U=3$ meV the TMR is enhanced (in modulus) for both on- and off-voltage regimes ($0 < t < 3$ ns and $t > 3$ ns, respectively). In particular the Coulomb interaction turns the TMR even more negative after the bias voltage is turned off, which reaches $\approx 40\%$ around 3.5 ns for $U=3$ meV.

IV. CONCLUSION

We predict novel spin-dependent effects in a quantum dot coupled to two ferromagnetic leads driven by a rectangular bias voltage pulse. Based on nonequilibrium Green function and master equation techniques we calculated the spin-resolved occupations and currents, the spin accumulation, and the tunnel magnetoresistance in the transient just after

\[
\frac{d}{dt}(n_{1}) = \frac{1}{e} (I_{1}^{L} + I_{1}^{R})
\]

\[
= \sum_{\eta} \Gamma_{\sigma}^{\eta} \left[ \tilde{f}_{\eta} n_{1} P_{\sigma} - (1 - \tilde{f}_{\eta}) P_{\sigma} - (1 - \tilde{f}_{\eta}) P_{2} \right].
\]  

(12)

and for the double-occupancy probability we have

\[
\frac{d}{dt}(n_{1,n_{1}}) = \sum_{\sigma} \Gamma_{\sigma}^{\eta} \left[ \tilde{f}_{\eta} n_{1} P_{\sigma} - (1 - \tilde{f}_{\eta}) P_{2} \right].
\]  

(13)
the bias voltage is turned on and off. Our main findings are
(i) a sign change of the spin accumulation as the time evolves in the P configuration, (ii) a spike of spin-\( \uparrow \) current in the emitter lead when the system is antiparallel aligned, and (iii) a time-dependent TMR that attains negative values. This negative amount can be further enhanced due to intradot Coulomb interactions.

40 The wideband limit consists of (i) neglecting the real part of the tunneling self-energy (level shift), (ii) assuming that the line-widths \( \Gamma_i \) are energy independent constants, and (iii) allowing a single time dependence \( \Delta_i(t) \) for the energies in each lead (Ref. 39).

41 For an analysis that does not rely on the wideband limit see J. Maciejko, J. Wang, and H. Guo, Phys. Rev. B 74, 085324 (2006).

42 The spin-independent version of this expression was originally obtained in N. S. Wingreen, A. P. Jauho, and Y. Meir, Phys. Rev. B 48, 4887(R) (1993).

44 In the present work \( \Gamma_i \ll k_B T \); i.e., we are at the sequential tunneling limit, so no coherent oscillations in the current are observed as in previous works (Refs. 38 and 42).

46 For an experimental setup to measure TMR in the presence of short voltage pulses, ranging from 0.5 to 500 ns, we address the reader to K. B. Klaassen, X. Xing, and J. C. L. van Peppen, IEEE Trans. Magn. 40, 195 (2004).

47 The effect of Coulomb interaction on time-dependent transport has been previously studied, e.g., by Q. F. Sun, J. Wang, and T. H. Lin, Phys. Rev. B 58, 13007 (1998), and also in Ref. 22 and Ref. 23.
