Multidirectional sorting modes in deterministic lateral displacement devices

Brian R. Long, Martin Heller, Jason P. Beech, Heiner Linke, Henrik Bruus, and Jonas O. Tegenfeldt

Abstract: Deterministic lateral displacement (DLD) devices separate micrometer-scale particles in solution based on their size using a laminar microfluidic flow in an array of obstacles. We investigate array geometries with rational row-shift fractions in DLD devices by use of a simple model including both advection and diffusion. Our model predicts multidirectional sorting modes that could be experimentally tested in high-throughput DLD devices containing obstacles that are much smaller than the separation between obstacles.

I. INTRODUCTION

Deterministic lateral displacement (DLD) is a mechanism of particle separation that uses the laminar properties of microfluidic flows in a periodic array of posts to sort particles based on size. This technique has been shown to differentiate between micrometer-sized particles with a resolution in diameter on the order of 20 nm. The basic sorting mechanism has been described for the devices used experimentally: Particles smaller than a critical radius \( r_c \) follow streamlines through the array while larger particles are systematically bumped laterally during each interaction with a post [1–3].

Previous analysis of DLD sorting has focused on predicting \( r_c \) as a function of array parameters, typically the width of the gap between posts and the shift of posts between rows. Once basic hydrodynamics is included, theoretical calculations of \( r_c \) agree with experimental results within about 5% [2,4,5]. Inclusion of diffusion in DLD sorting has been described using rough estimations [1–3], and in more detailed studies that incorporate both microfluidic advection and diffusion to calculate \( r_c \) under a range of experimental conditions [5].

Previous analysis of the geometry of the DLD array has been limited to the following conventional case. In a given row the center-to-center distance between the posts is denoted \( \lambda \), see Fig. 1. The subsequent row of posts is placed at a distance \( \alpha \lambda \) downstream from the first row. Normally, \( \alpha \) is chosen to be unity, however this is not an essential requirement. The posts in this second row are displaced a distance \( (1/N)\lambda \) along the row, where \( N \) traditionally has been an integer. The ratio \( 1/N \) is also denoted the row-shift fraction \( \epsilon \). In row number \( N+1 \) the posts have the same positions as in the first row, and consequently the array is cyclic with period \( N \). Due to this periodicity of the array and the laminarity of the flow, the stream can naturally be divided into \( N \) flow lanes, each carrying the same amount of fluid flux, and each having a specific path through the device [1].

For devices with the simple row-shift fraction \( \epsilon = 1/N \) and disregarding particle diffusion, only one critical separation size \( r_c \) is introduced. Spherical particles with a radius smaller than \( r_c \) will move forward along the main flow direction through the device, defining the angle \( \theta = 0 \). However, particles with a radius larger than \( r_c \) are forced by collisions with the posts to move in a skew direction at an angle \( \theta \) given by \( \tan \theta = 1/(\alpha \lambda) \). Taking diffusion into account the transition from straight to skew motion takes place over a finite range of particle sizes [1–3,5].

In this paper we generalize the array geometry by studying the effects of row-shift fractions different from that of the conventional, simple \( 1/N \) array. We show in Sec. II that by displacing consecutive rows by the rational fraction \( \epsilon \lambda = (M/N)\lambda \), where \( M \) is an integer that is not a divisor of \( N \), two new separation modes appear, each associated with a distinctive range of particle sizes and separation directions \( \theta \). Furthermore, to test experimental feasibility of the separation modes, we introduce in Sec. III a model of the DLD system reduced to its essential elements: Particle trajectories interrupted by size-dependent interactions with a periodic array of posts. Utilizing these simplifications, we investigate in Sec. III the advection and diffusion of particles in the \( M/N \)-array geometries, and discuss in Sec. IV possible experimental consequences of our DLD system.

In our model of the DLD system described in Sec. III we reduce the posts to pointlike obstacles in a uniform flow. This particular case is currently of interest to researchers looking to apply DLD separation to high-throughput microfluidic devices. Such a reduced post size decreases hydraulic resistance and thus increases the liquid throughput for a given pressure difference applied along the device. One promising method to create such devices is to use arrays of semiconductor nanowires [6] in a microfluidic channel.

II. BASIC THEORETICAL ANALYSIS

The introduction of a nonsimple row-shift fraction \( \epsilon = M/N \) in the DLD system is first discussed in Sec. II A for the specific case of \( M/N = 3/8 \), since all the separation modes are present in that device geometry. Figure 1 shows the principle of the fractionally displaced DLD array leading...
to multidirectional separation of particles of different sizes. As was the case for the simple row-shift fraction 1/N, the rational row-shift fraction M/N also naturally leads to N flow lanes, each carrying the same amount of fluid flux. In this section, all particles are assumed to follow these flow lanes unless bumped by an interaction with a post. However, in contrast to the traditional DLD geometries, the posts are displaced M flow lanes instead of just a single flow lane when passing from one row of posts to the next.

In Sec. II B we analyze this more general case of M/N arrays, where the integer row-shift M and the integer array-period N have no common divisors.

A. Specific row-shift fraction 3/8

First we consider the explicit choice of parameters given in Fig. 1, namely, a period N=8, and a row shift of M=3 lanes in the y direction εy, i.e., a row-shift fraction of ε =3/8. The flow v is in the x direction εx. For simplicity, we employ the most simple model where all flow lanes are assumed to have the same width λ/N, and where the particles are not subject to Brownian motion. The analysis can straightforwardly be extended to take the different widths of the flow lanes [2] as well as diffusion [5] into account.

The analysis is most easily carried out by considering spherical particles of increasing radius r. As the rows in Fig. 1 are shifted to the right, it is natural to choose the starting point of a given particle to be directly to the right of a post, placing the particle’s center in flow lane R=1, 2, 3, or 4 according to size.

For the smallest particles with r<λ/N, labeled A in Fig. 1, we obtain a path corresponding to the familiar so-called zigzag path defined in Ref. [1]. Due to the point-like nature of our obstacles, the path is a straight line, indicated by the dashed vertical line in Fig. 1. The path angle is θA =arctan 0=0°. For the next set of particles with λ/N<r<2λ/N (B+ in Fig. 1), we note that they are not affected significantly by passing the second rows of posts. The displacement of (M/N)λ is larger than the size of the particle. By simple inspection we find that the particles interact with a post in the fourth row leading to a bump of one lane width to the right. This bumping brings the particles back to a position just right of a post, and we have identified a new separation mode, B+. The direction of mode B+ can be characterized by the integers

\[ p = \text{the number of rows after which the bumping pattern repeats itself, and} \]

\[ q = \text{the number of flow lanes that the particles are bumped to the right while travelling through } p \text{ rows.} \]

Here, with p=3 and q=1 and the array parameters indicated in Fig. 1, the path angle of mode B+ is found to be θB+ =arctan[1/(α×3×8)]≈2.4°. Here and in the following we choose the aspect ratio α=1.

For the third set of particles with 2λ/N<r<3λ/N, marked as B− in Fig. 1, we note that they collide with a post in the second row and are bumped two lanes to the left. After two rows, the particles are again bumped two lanes to the left, and we have identified another new separation mode, B−. Given this period p=2 bumping of q=−2 flow lanes (where minus indicates displacement to the left), the path angle of mode B− is found to be θB− =arctan[−2/(α×2×8)]≈−7.1°.

Finally, the fourth set of particles (with 3λ/N<r) is considered, shown as the large light gray circle in Fig. 1. Since 3λ/N equals the row-shift εx, these large particles collide with a post in each row (p=1) where they are bumped q =M=3 lanes to the right. This is the conventional maximal
displacement mode \( C \) [1]. As a result, the path angle for mode \( C \) here is found to be \( \theta_C = \arctan[3/(\alpha \times 8)] = 20.6^\circ \).

### B. General row-shift fractions \( M/N \)

In the general case of a DLD device with period \( N \) and a row shift of \( M \) flow lanes, it is useful to introduce the floor function \( [x] \) of \( x \), which gives the largest integer smaller than or equal to \( x \), e.g., \([8/3]=2\) and \([10/3]=3\), and the ceiling function \( \lceil x \rceil \) of \( x \) which gives the smallest integer larger than or equal to \( x \) (see also the definitions given at Ref. [7]).

Using the notation in Fig. 1, the flow lane \( R \) occupied by the center of the particles can be expressed in terms of the particle radius \( r \) as \( R = [rN/\lambda] \), so that \( R = 1, 2, 3, \ldots, \lfloor N/2 \rfloor \) for \( 0 < r < \lambda/2 \).

Two cases are straightforward to analyze. For small radii with \( R = 1 \), the particles will follow the streamlines without any systematic net lateral displacement, i.e., a mode \( A \) in the direction \( \mathbf{t}_A \) given by

\[
\mathbf{t}_A = \alpha \mathbf{e}_x,
\]

and forming the path angle \( \theta_A \) with the \( x \) axis,

\[
\theta_A = 0, \quad R = 1.
\]

For large radii with \( M < R < \lfloor N/2 \rfloor \), the particles collide with the posts and are bumped \( M \) flow lanes to the right in each row, but they do not get stuck between the posts; this is mode \( C \). The path is directed along the direction \( \mathbf{t}_C \) given by

\[
\mathbf{t}_C = \alpha \mathbf{e}_x + \frac{M}{N} \mathbf{e}_y,
\]

and forming the path angle \( \theta_C \) with the \( x \) axis,

\[
\theta_C = \arctan \left( \frac{M}{\alpha N} \right), \quad M < R < \left\lfloor \frac{N}{2} \right\rfloor.
\]

In a given \( M/N \) array, modes with larger sorting angles are excluded because of the post spacing in the \( y \) direction: Particles with radius \( r > \lambda/2 \) are unable to fit between the posts.

If the particles are small enough to pass the second row without getting bumped to the right, but too large for mode \( A \), \( 1 < R \leq M \), their trajectories fall into one or two \( B \) modes.

As a particle is convected through the array, a post will approach the particle from the left in steps of its center to the left of this obstacle and will therefore enter mode \( B_1 \) where it is displaced to the left with a period \( p_1 = \lfloor N/2 \rfloor \). This is most readily seen by starting the analysis with a particle position just left of a post. A particle with \( (N \mod M) < R < \lfloor (N-R+1) \mod M \rfloor \) will bump left after \( p_1 = \lfloor N/2 \rfloor \) rows and will again be in a position just left of a post. The small particle in mode \( B_1 \) of Fig. 2 is an example of this behavior. Slightly larger particles with \( \lceil (N-R+1) \mod M \rfloor < R \leq M \) will bump right after \( p = \lfloor M/2 \rfloor \) rows. Since we are only considering particles with \( R \leq M \), this displacement will always be less than \( M \) flow lanes, and the particle is therefore bound to bump left on the post in the following row, i.e., after a total of \( p_1 = \lfloor N/2 \rfloor \) rows. The large \( B_1 \) mode particle in Fig. 2 is an example of this behavior.

The trajectories in mode \( B_1 \) have period \( p_1 = \lfloor N/2 \rfloor \). The number \( q_1 \) of lanes bumped after passing these \( p_1 \) rows is \( q_1 = Mp_1 - N < 0 \). The path is directed along the direction \( \mathbf{t}_{B_1} \) given by

![FIG. 2. An array with period \( N=10 \) and a shift of \( M=3 \) flow lanes per row, giving a row-shift fraction \( \epsilon=3/10=0.3 \). The flow \( \mathbf{v} \) is directed along the \( x \) axis from top to bottom. Here there are three sorting modes, delimited by two critical radii. Mode \( A \) for particles of radius \( r \) with \( r < r_A = (1/10)\lambda \) (shown on the far left-hand side), and mode \( C \), the maximal displacement mode for \( (3/10)\lambda = r_C < r < (1/2)\lambda \) (large light gray circles). A mode \( B_1 \) displaces particles with \( r_A < r < r_C \) towards the left (large dark gray and intermediate, light gray circles).](image-url)
\[ t_{B_+} = \alpha p_x e_x + \frac{q_r}{N} e_y, \]  
\[ p_+ = \left\lfloor \frac{N + R}{M} \right\rfloor, \]  
\[ q_+ = M p_+ - N > 0, \]

forming the path angle \( \theta_{B_+} \) with the x axis,

\[ \theta_{B_+} = \arctan \left( \frac{q_r}{\alpha p_x N} \right) < 0. \]  

If \( 1 < R \leq (N \mod M) \) the particle will enter mode \( B_+ \) where it is displaced to the right with a period \( p_+ = \left\lfloor \frac{N + R}{M} \right\rfloor \). To realize this it is natural to start the analysis with the particle just right of a post. Again, a post will approach the particle from the left in steps of \( M \) lanes as the particle moves through the array. A particle with \( 1 < R \leq \frac{N}{M} \) will follow the flow for \( p_+ = \left\lfloor \frac{N + R}{M} \right\rfloor \) rows and then bump right. If \( \frac{N}{M} < R \leq (N \mod M) \) the particle will bump left already in the second row of posts. The particle is now in a position just left of a post. However, since it is not large enough to follow the \( B_- \) path, it will bump right when it meets the post after \( p_+ = \left\lfloor \frac{N + R}{M} \right\rfloor \) rows.

The trajectories in mode \( B_+ \) have period \( p_+ = \left\lfloor \frac{N + R}{M} \right\rfloor \). After \( p_+ \) rows the particles will get bumped \( q_+ \) flow lanes to the right given by \( q_+ = M p_+ - N > 0 \). The path is directed along the direction \( t_{B_+} \) given by

\[ t_{B_+} = \alpha p_x e_x + \frac{q_r}{N} e_y, \]  
\[ p_+ = \left\lfloor \frac{N + R}{M} \right\rfloor, \]  
\[ q_+ = M p_+ - N > 0, \]

forming the path angle \( \theta_{B_+} \) with the x axis,

\[ \theta_{B_+} = \arctan \left( \frac{q_r}{\alpha p_x N} \right) > 0. \]  

In terms of the flow lane number \( R \), the criteria for the four different displacement modes can be summarized as follows:

mode A if \( R = 1 \),  
mode \( B_+ \) if \( 1 < R \leq (N \mod M) \),  
mode \( B_- \) if \( (N \mod M) < R \leq M \),  
mode C if \( M < R \leq \left\lfloor \frac{N}{2} \right\rfloor \).

Note that mode \( B_+ \) vanishes if \( (N \mod M) = 1 \).

</table>

The results for $D=0$ for particles with radii $r<r_{11}$ (mode $A$), $r_{11}<r\leq r_{12}$ (mode $B$), and $r>r_{12}$ (mode $C$). (b) Particles, with the same radii as in (a), moving through the array with a flow speed of $v=100 \mu m/s$, including the effect of diffusion. Broadening of all distributions due to diffusion can be seen and particles in mode $C$ are sorted less efficiently. Initial spatial distributions here are the same for all particle radii, and a narrow initial distribution is used for visual clarity.

employing the implicit time $t=x/v$ set by convection along the $x$ direction, and using the Fourier cosine transformation in the transverse $y$ direction as described below.

The computation uses a finite array of width $w=10\lambda$, i.e., containing 10 posts, and the row separation is again taken to be equal to the post separation, i.e., $\alpha=1$. The array with width $w$ is discretized in $y$ into $n_{max}=10^4$ pixels of size $\Delta w \times \Delta x$ with $\Delta x=\Delta w=w/n_{max}$.

The discrete Fourier cosine transformation $C(x,k_n)$ of the distribution $c(x,y)$ then takes the form

$$C(x,k_n) = \frac{2}{w} \int_0^w c(x,\tilde{y}) \cos(k_n \tilde{y}) d\tilde{y},$$

where $k_n$ is given by

$$k_n = \frac{2\pi}{w} n, \quad n = 0, 1, 2, \ldots, n_{max} = \frac{w}{\Delta w}.$$  

By direct inspection we find the well-known result from the $y$-dependent diffusion equation in Fourier space that, during the time step $\Delta t=\Delta x/v$, $C(x,k_n)$ evolves into $C(x+\Delta x,k_n)$ as

$$C(x+\Delta x,k_n) = C(x,k_n) \exp \left( -Dk_n^2 \frac{\Delta x}{v} \right).$$

By the inverse Fourier cosine transform we can therefore write the distribution at row $x+\Delta x$ in terms of that at row $x$ as

particles is then added to the distribution in the adjacent pixels to maintain the total number of particles (see Fig. 3).

(2) The distribution $c(x,y)$ is subsequently evolved in accordance with the diffusion equation, with the diffusion coefficient given by Eq. (11),

FIG. 3. (Color online) Composite image of numerically calculated spatial distributions for a device with $N=10$ and $M=3$. (a) Results for $D=0$ for particles with radii $r<r_{11}$ (mode $A$), $r_{11}<r\leq r_{12}$ (mode $B$), and $r>r_{12}$ (mode $C$). (b) Particles, with the same radii as in (a), moving through the array with a flow speed of $v=100 \mu m/s$, including the effect of diffusion. Broadening of all distributions due to diffusion can be seen and particles in mode $C$ are sorted less efficiently. Initial spatial distributions here are the same for all particle radii, and a narrow initial distribution is used for visual clarity.

$$\frac{\partial c}{\partial x} = D \frac{\partial^2 c}{\partial y^2},$$

046304-5
distributions are calculated without diffusion. In mode A, where $r = r_{c1} = (1/N)\lambda$, particles may interact with the posts, but no net lateral displacement is accomplished. Mode C is characterized by a displacement equal to the shift $(M/N)\lambda$ for every row the particles pass through. In the mode $B_2$, particles of size $r_{c1} < r < r_{c2}$ interact with posts more frequently than in mode $A$ but less frequently than in mode $C$, as described in Sec. II B. The 3/10 array used here clearly exhibits the lone $B_2$ mode shown in Table I for these array parameters. It is important to note that mode $B_2$ vanishes in the conventional case $M = 1$, and all particles smaller than the critical radius $r_{c2}$ move along the direction of flow.

The directions $t_A$ and $t_C$ of the conventional modes $A$ and $C$ are given directly by Eqs (2) and (4) for $\alpha = 1$,

$$t_A = e_x,$$

$$t_C = e_x + \frac{3}{10} e_y,$$

while the direction $t_B$ of mode $B_2$ is found through the path period $p_2 = |\frac{2p}{M}| = |\frac{10\upsilon}{v}| = 3$ and the lane shift $q_2 = pM - N = 3 \times 3 - 10 = -1$, and thus

$$t_B = 3e_x - \frac{1}{10} e_y.$$

The corresponding displacement angles become

$$\theta_A = 0.0^\circ, \quad 0 \frac{\lambda}{10} < r < 1 \frac{\lambda}{10},$$

$$\theta_B = -1.9^\circ, \quad 1 \frac{\lambda}{10} < r < 3 \frac{\lambda}{10},$$

$$\theta_C = 16.7^\circ, \quad 3 \frac{\lambda}{10} < r < 5 \frac{\lambda}{10}.$$

The array parameters used here can be translated into those used in DLD literature [1–3], simply by setting $M = 1$.

**Effect of diffusion on sorting.** The effect of diffusion on the sorting of particles is shown in Fig. 4. The angles shown are measured between $v$ and the lateral displacement of the center of mass of the distribution for each particle size after 10 rows of posts for high and low flow speeds. We can estimate speeds at which diffusion becomes negligible by comparing the time it takes a particle to be advected along the $x$ direction from one row to the next, $\lambda/\upsilon$, to the time it takes a particle to diffuse transversely in the $y$ direction to reach a position where it would be bumped, $2D/(r_{c2})^2$. For high flow speeds,

$$v \gg \frac{2D\lambda}{(r_{c2})^2},$$

diffusion can be neglected, and the transitions between the sorting modes are sharp, as seen in the $D = 0$ case. Note that this velocity diverges as the particle size approaches the critical radius $r_{c2}$; in this limit the displacement needed for a particle to change sorting directions goes to zero. Within the spatial resolution of this work (1 pixel = 10 nm), the particles closest in size to the critical radius will still be sensitive to diffusion at flow velocities below 10 mm/s. As flow speeds
decrease, particles have more time to diffuse transversely as they move through the array, and the effects of thermal motion on sorting are seen more clearly. Transverse diffusion of particles along the y direction tends to shift the center of mass of the distribution \( r(x, y) \) towards the midpoint between posts. This means that particles with \( r < r_c = \frac{3}{10} \) are more likely to be shifted to higher sorting angles. However, in the regions between rows, diffusion allows particles to move transversely away from the path that would normally be “bumped” by a post, decreasing their sorting angle. These two effects of diffusion are responsible for the smoothing of the angle versus radius curves for slower flow speeds in Fig. 4. The calculated values for \( \theta_{B^+} \) are in good agreement with the value predicted in Eq. (18a), but for particles with \( r > r_c = \frac{3}{10} \), the finite width of the initial distribution and the relatively short array size (10 rows) reduce the calculated values for \( \theta_C \) from the predicted value by about 15%. The small variation in sorting angle with radius for modes \( B^- \) and \( C \) for \( D=0 \) in Fig. 4 is mainly the result of the two end points used to define the angle being not exactly equivalent. The position of the second, but not the first end point varies continuously with bead size, and so the presented angle varies with bead size. Second, since the number of rows is not divisible by the periodicity of mode \( B^- \), an additional small error is introduced. These deviations should vanish for simulations with larger numbers of rows.

IV. DISCUSSION

A. Sorting mode \( B \) and its relation to kinetically locked-in transport

DLD devices have thus far been made with a fixed flow direction and almost exclusively with \( M=1 \). However, in theoretical work studying transport through periodic potential landscapes, the direction of the applied force is varied for a fixed array geometry and the transport direction is calculated \([9\text{–}12]\). To calculate the correspondence between varying the array parameters \( M \) and \( N \) used here and changing the flow direction in a fixed array as in \([9\text{–}12]\) is cumbersome, but for a range of flow directions near \( t_B \equiv \frac{3}{10} \), the angles to the flow direction \( \theta_B \) and \( \theta_C \) vary as the flow direction changes, but the relative angle between them, \( \theta_C - \theta_B \), remains a constant defined by the array. The angle between modes \( B^- \) and \( C \) is insensitive to small changes in flow direction for \( v \) near (in this case) \( 3e_y - \frac{1}{10}e_x \).

This insensitivity to flow direction is an example of a plateau in a so-called devil’s staircase: Transport through a two-dimensional (2D) periodic potential is independent of the flow direction near small integer lattice vectors \([9]\). In this case, the lattice vectors are \( a_1 = t_c = e_y + (3/10)e_x \) and \( a_2 = e_x \), and the two close-lying flow directions are \( t_B = 3e_y - \frac{1}{10}e_x = 3a_1 - a_2 \) and \( a_1 - t_c \).

The interplay between lattice directions and applied forces has been documented extensively in the literature of kinetically and statistically locked-in transport. Of interest in the present context is that many numerical simulations of trajectories through various two-dimensional periodic potentials have been done to study these and other phenomena, including sorting of particles \([9\text{–}12]\).

The interaction between posts and particles that we have chosen simplifies DLD to a one-dimensional (1D) distribution that evolves in time. This allows the effects of diffusion to be easily incorporated into our modeling of the dynamics of the distribution of particles. Also, the particular interaction between point-sized posts and finite-sized particles depends only on particle size, an analysis that seems to be absent from the literature.

B. Diffusion, detectability, and experimental possibilities

A clear difference between the results in Fig. 4, based on zero-sized posts, and those reported in the literature, based on finite-sized posts, is that the critical radius (defined as the inflection point of the angle versus radius graph near \( r=r_c \), decreases for lower flow velocities in Ref. \([1]\), whereas our simulations show a critical radius that is essentially constant. When particles have more time to diffuse laterally in reported experimental data, ones that previously followed the zigzag path follow something closer to mode \( C \) but not the other way around. We have identified the difference in size of the posts as the primary basis for the difference in symmetry. In the gap between the posts, only beads smaller than \( r_c \) can change modes (from \( A \) to \( C \)) whereas, beads larger than \( r_c \) cannot change modes because of steric hindrance. Diffusion between posts is thus asymmetric. On the other hand, between rows all beads can change modes equally well so that the effect of diffusion is symmetric. This result is most clearly seen in two cases: (i) With sufficiently large posts and small spacing between rows, diffusion between posts dominates leading to asymmetry, and (ii) with our needlelike posts, instead diffusion between the rows dominates, leading to symmetry between small and large particles. In devices with large round posts such as those in Ref. \([1]\), the flow streams are narrower in the gap between the posts than in the region between the rows making the asymmetric diffusion even more pronounced. The symmetry about \( r_c \) shows that sorting in this model is robust against changes in flow velocity.

As discussed in Sec. IV A, there is no difference between modes \( A \) and \( B^- \) when the flow is directed along the lattice direction \( 3a_1 - a_2 \), which is equivalent to a conventional array with \( M=1 \) and \( N=3 \), instead of along \( e_x \). Also, while mode \( B^- \) for the \( 3/10 \) array shown in Fig. 2 is directed away from mode \( C \), the mode \( B^- \) discussed in Sec. II A is deflected away from \( v \) towards mode \( C \). The absence of modes \( B^- \) and \( B_+ \) in previous analyses of DLD experiments stems from the use of tilted square arrays with flows chosen such that \( M = 1 \) or more general arrays that are still limited to simple row shifts \( 1/N \). In these cases, modes \( A \) and \( B \) are the same: They both go along the direction of flow. Interestingly, in their paper \([2]\), Inglis et al. mention that they are studying simple row-shift fractions \( e = 1/N \), with \( N \) being an integer, but they do not comment on the data points in their Fig. 2 that clearly have \( e \neq 1/N \).

Experimental detection of mode \( B \) requires that the distributions of modes \( A \) and \( B \) must be spatially separated. The
FIG. 5. (Color online) Distributions of three particle sizes: $r = 0.90$ (dashed line), $2.00$ [(red, gray), and $3.08 \mu m$ (black)] after transport through 10 rows of the $N=10, M=3$ array. The total number of particles is the same in each case and each initial distribution (not shown) is a square distribution with a narrow width centered on $y=30 \mu m$. (a) No diffusion. (b) With diffusion and $v = 1000 \mu m/s$. (c) With diffusion and $v = 100 \mu m/s$. (d) With diffusion and $v = 10 \mu m/s$. Panel (b) shows a case where mode $B_-$ could be detected experimentally. For the lower speed in panel (c), modes $A$ and $B_-$ cannot be resolved, but the combined distribution is broader than mode $A$ alone. For the even lower speed in panel (d) the distributions of particles in modes $A$ and $B_-$ are each wider than the separation between them and the two modes are completely unresolvable.

The numerically calculated distributions shown in Fig. 5 exhibit four qualitative regimes that could be observed in an experiment to detect the presence of particle transport in mode $B$.

(a) At very high flow speeds, corresponding to $D=0$ in the numerical data, the three modes are completely separated because each distribution is very narrow. In this regime, arbitrary spatial separation can be achieved simply by running the particles through a longer array.

(b) At high intermediate flow speeds, the distributions have widened due to diffusion, but modes $A$ and $B$ are clearly distinguishable, despite some overlap.

(c) At low intermediate flow speeds, modes $A$ and $B$ overlap enough to prevent resolution of two separate distributions. This regime is relevant to DLD device design because it would be experimentally observed as an anomalous, asymmetric broadening of the distribution associated with the zigzag path.

(d) At low flow speeds, distributions from modes $A$ and $B$ are completely overlapping and it may even be difficult to differentiate them from mode $C$.

Experimental realization of the regime investigated in this model would require arrays made with very small posts to minimize hydrodynamic effects on particle trajectories. This also corresponds to a reduction in hydrodynamic drag, which is beneficial for researchers seeking to increase fluid throughput of devices.

As can be seen in Fig. 3, the angle $\theta_b$ is small compared to $\theta_c$. In order to differentiate between particles traveling in modes $A$ and $B$, size dispersion of beads must be considered in addition to broadening due to diffusion. Commercially available polystyrene beads used in DLD experiments typically have size distributions with widths of less than $\pm 10\%$. This then requires choosing particles whose size distributions are separated by more than $10\%$, such as those shown in Fig. 5, or the use of a DLD array to create a sufficiently narrow size distribution. If hydrodynamic effects or limitations on flow velocity in a particular experiment prevent the sorting mode from being completely resolved, it may still appear as an asymmetric broadening of the distribution of seemingly undeflected particles, as in Fig. 5.

In general, the separation angles for a given $M/N$ array can be made larger to the extent that the aspect ratio $a$ can be made smaller without risking clogging of the largest particles. By consulting Table I, it can be seen that the separation angle of the $3/10$ array is one of the smaller $B$ angles, and also, the $3/8, 3/11, 4/11,$ and $5/12$ arrays offer both the $B_+$ and the $B_-$ modes.

V. CONCLUSIONS

We have identified sorting modes in a model of transport through a DLD device characterized by row-shift fractions $M/N$. Our simple model also reproduces key features of DLD arrays, including sorting based on size and the blurring of cutoffs between modes due to diffusion. Even if not completely resolved, the sorting mode has the potential to increase spatial broadening of zigzag particle distributions. In order to avoid this broadening, adjustable DLD arrays could use variable spacing while maintaining a fixed $M=1$ geometry, such as in Ref. [4], or tune flow angles to exactly reproduce the $M=1$ condition across a fixed obstacle array using techniques such as in Ref. [13]. Our simulations indicate that using needlelike posts decreases the shift in critical size due to diffusion that has been observed in devices where the post separation is on the same scale as the post diameter. Furthermore, the use of more general array geometries and simplified fluid dynamics links this work to the field of kinetically locked transport phenomena.
