We have calculated the I-V characteristics of short chains of C\textsubscript{20} molecular cages between Al and Au leads with an ab initio formalism. The results indicate that a linear chain of such molecules acts primarily as metallic nanowires. The transmission, however, depends sensitively both on the orientation and distance between the individual C\textsubscript{20} molecules. Transport through the molecular chains is accompanied by a significant amount of charge transfer, which remains localized at the electrode/molecular interface.

DOI: 10.1103/PhysRevB.65.041401  PACS number(s): 72.80.-r

The recent advent of nanometer electro-mechanical systems (NEMS) has attracted considerable attention, both for practical application purposes and as a fundamental area of research.\textsuperscript{1-7} Despite the impressive progress achieved, the physics of many important issues still needs to be resolved before NEMS becomes a viable technology. For example, inherent in the problem of quantum transport through NEMS is the strong coupling between the atomic and the electronic degrees of freedom. At a truly molecular scale, how then does the coupling of the different functional units affect the electron transport? What is the role of the electrode-molecular interaction? Which factors critically influence current flow? All these questions need a thorough investigation in order to gain fundamental understanding of the operation of NEMS devices.

In this paper, we report on an ab initio investigation of these issues for a NEMS device consisting of a short chain of C\textsubscript{20} cages between atomistic Al and Au leads. This choice is motivated by the recent fabrication of fullerene-based NEMS devices such as the C\textsubscript{60}-amplifier.\textsuperscript{1} Because the C\textsubscript{20} cage is the smallest fullerene, it represents a useful model for prototypical fullerene-based devices that are at the same time numerically tractable. The C\textsubscript{20} cage is the ground-state structure of the C\textsubscript{20} clusters, within density-functional theory.\textsuperscript{8,9} It has a relatively small gap of 0.96 eV between highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) and a chain of them provides insight as to how molecules may, or may not, act as resistors when arranged in series. Our main results are the following. Surprisingly, the chains display current-voltage (I-V) characteristics similar to that of metallic nanowires. However, depending on the relative orientation of the C\textsubscript{20} molecules with respect to each other, the chains display either a strong or weak dependence on the number of molecules in the chains, which may be understood in terms of the formation of an effective tunneling barrier. Transmission through the chains is also characterized by a considerable amount of charge transfer from the electrodes to the cages, which depends strongly on the type of electrode material and the electrode/molecular distance.

The C\textsubscript{20} fullerene (CF) consists of twelve pentagons arranged in a cage structure, as shown in Fig. 1. To construct a C\textsubscript{20} chain, many different atomistic arrangements are possible, but for simplicity we have concentrated on the following.\textsuperscript{10} The chains are characterized by two important lengths: the electrode/C\textsubscript{20} distance \(d_1\), and the distance \(d_2\) between each of the C\textsubscript{20} molecules. In terms of the molecular orientation, we have focused on the two cases shown in Fig. 1. The molecules are arranged such that the C atoms are either directly opposite (top configuration CF1) as is characteristic of polymerized fullerenes,\textsuperscript{8,9} or maximally incommensurate with respect to each other (lower configuration CF2).

To calculate the I-V curves, we made use of a recently developed formalism\textsuperscript{12} that combines the Keldysh nonequilibrium Green’s functions (NEGF)\textsuperscript{13,14} with pseudopotential-based real-space ab initio density-functional theory.\textsuperscript{15} The main advantages of this approach are (i) a proper treatment of the open-boundary conditions for the system as appropriate for quantum transport under an external bias voltage; (ii) an atomistic treatment of the electrodes; and (iii) a self-consistent calculation of the charge density via NEGF thereby incorporating the effects of both the scattering and bound states present in the system. Details about this methodology can be found in Ref. 12.

Figure 2 shows the I-V curves for the short C\textsubscript{20} chains, with up to four molecules, coupled to either Au or Al-(100) leads. All of the I-V curves have a significant nonzero slope, indicating conduction. Hence, to first order, all the chains act as metallic nanowires. However, there are some differences in the results as obtained via CF1 and CF2. First, given a similar \(d_1\) from the electrodes, the I-V characteristics for

![FIG. 1. Atomic configuration of the central scattering region of a typical chain of two C\textsubscript{20} molecules between Al(100) leads: (a) CF1; (b) CF2. The arrow marks the intermolecular distance \(d_2\).](image-url)
chains in CF1 have a somewhat larger slope, as compared to those in CF2. This may be understood in terms of a larger overlap, and, therefore, a better coupling between the orbitals on the different C₂₀ molecules in CF1. For the most part, for chains with C₂₀’s in CF2, the I-V curves are very similar, lying virtually on top of each other. The exception to this appears to be that of a single C₂₀ molecule coupled to Au leads, which has a very much larger slope than all the other curves. This slope is, however, comparable to what is obtained for longer chains in CF1 between Au leads. Similar to the results for the CF1 chains, the I-V curves in this case are virtually identical, although there is a bit of a numerical deviation for the four C₂₀ chain under positive bias voltages. Nevertheless, the overall behavior of these curves is quite similar. For Al leads, there is a reduction in the slopes, that manifests itself primarily under larger biases. For smaller biases, the curves for the three and four molecules are quite similar and overlap. Hence, in general, there appears to be no dramatic reduction in the I-V slopes as the number of molecules is progressively increased.

This result is somewhat surprising, generally speaking one would expect the formation of an effective barrier through which the electrons need to tunnel. The presence of such barriers would definitely lead to a strong length-dependent resistive behavior. However, there is no clear evidence of such a barrier. These results, therefore, differ, with the exception of Al in CF1, from the previously analyzed cases of linear C chains,[16,17] which are characterized by significant variations in the I-V slopes as the number of C-atoms is increased, along with even-odd oscillations in the I-V curves.[16,17]

Quantum transport through the C₂₀ cages is accompanied by a significant charge transfer from the electrodes to the molecules, which acts not only to align the Fermi level of the system, but also builds up a Schottky barrierlike structure through the formation of an interface dipole. Such charge doping has previously been noted for the case of chains of C atoms coupled to Jellium leads.[16] However, our use of atomic leads allows us to investigate this process in detail. Analysis shows that for the C₂₀ chains, more than 90% of the transmission takes place through the LUMO states, which are partially filled because of the charge transfer. The amount of charge transferred depends both upon the electrode material and the distance of the lead, where it comprises about 12% of the total charge on a single-C₂₀ molecule. This transferred charge decreases rapidly with distance, and ultimately comes to represent only about 2.5% of the total charge. These relatively large variations in the charge transfer with distance manifest itself in the very sensitive behavior of I-V curves: even very small changes in this distance can lead to significant changes in the slopes of the I-V curves, which essentially interpolate between the results obtain with CF1 and CF2.

Table I summarizes the amount of charge transferred to each of the C₂₀ molecules within the different chains. First, it is clear that there are only small variations as a function of the bias voltage. Second, the amount of charge transferred is mostly independent of the number of molecules in a given chain, and the internal C₂₀ conformation CF1 or CF2. This is a reflection of the internal charge distribution within the chains. Almost all of the transferred charge is located on the C atoms closest to each of the electrodes, where they form significant multipoles. As expected, while there is an increase in the C-atom charges, there is a corresponding charge depletion for electrode atoms closest to the C₂₀ molecules that almost exactly cancel each other. At the lowest order, the charge distribution is characterized by its dipole moment, for which typical magnitudes of 20.2, 14.0, and 12.0 D are obtained for Al leads and distances of 1.53, 1.85, and 3.44 Å, respectively. However, it must be emphasized that all of the charge distribution have a significant quadrupole moment as well, whose contributions to the interface potential appears to be significant. Finally, note that only a small amount of the

The open circles denote the charge transferred to the middle molecule of a three C₂₀ chain as a function of the intermolecular distance d₂.](Image)
transferred charge, $\sim 0.5e$, is associated with all of the internal C$_{20}$ molecules. Since such molecules are relatively far away from the electrodes, this charge is mostly independent of the electrode characteristics. It does, however, depend very weakly on $d_2$ as summarized in Fig. 3.

As may be expected, transport through the chains is quite sensitive to the intermolecular distance $d_2$, especially when the molecules are in configuration CF1. Figure 4 shows some typical results for two C$_{20}$ molecules between Al leads. When the distance between the two molecules is very close, there is relatively little transport through device with a flat $I$-$V$ curve. As the C$_{20}$’s are moved further apart, the slopes of the $I$-$V$ curves increase and the device displays full metallic behavior that is maximal at a distance of $\sim 2.4$ Å. Increasing the distance even further leads to a general decrease in the conductance, with the $I$-$V$ curves even displaying some negative differential resistance behavior. We thank Vincent Meunier for valuable discussions, and acknowledge financial support from NSERC of Canada and FCAR of Quebec (H.G.). We also thank the North Carolina Supercomputing Center (NCSC) for extensive computer support.
