Abstract

As solid oxide fuel cell (SOFC) technology is moving closer to a commercial break through, lifetime limiting factors, determination of the limits of safe operation and methods to measure the “state-of-health” of operating cells and stacks are becoming of increasing interest. This requires application of advanced methods for detailed electrochemical characterisation during operation. An operating stack is subject to steep compositional gradients in the gaseous reactant streams, and significant temperature gradients across each cell and across the stack, which makes it a complex system to analyse in detail. Today one is forced to use mathematical modelling to extract information about existing gradients and cell resistances in operating stacks, as mature techniques for local probing are not available. This type of spatially resolved information is essential for model refinement and validation, and helps to further the technological stack development. Further, more detailed information obtained from operating stacks is essential for developing appropriate process monitoring and control protocols for stack and system developers.

An experimental stack with low ohmic resistance from Topsoe Fuel Cell A/S was characterised in detail using electrochemical impedance spectroscopy. An investigation of the optimal geometrical placement of the current probes and voltage probes was carried out in order to minimise measurement errors caused by stray impedances. Unwanted stray impedances are particularly problematic at high frequencies. Stray impedances may be caused by mutual inductance and stray capacitance in the geometrical set-up and do not describe the fuel cell. Three different stack geometries were investigated by electrochemical impedance spectroscopy.

Impedance measurements were carried out at a range of ac perturbation amplitudes in order to investigate linearity of the response and the signal-to-noise ratio. Separation of the measured impedance into series and polarisation resistances was possible.
1. Introduction

The DOE lifetime target for Solid Oxide Fuel Cells (SOFCs) stacks is 60,000 h by 2020 for stationary applications [1]. Understanding and mitigation of the degradation mechanisms in SOFC stacks is therefore crucial in order to improve the durability and increase the stack lifetime [2].

Electrochemical Impedance Spectroscopy (EIS), is a powerful diagnostic technique that can increase understanding of the degradation mechanisms dominating in operating stacks since the technique may provide information on individual losses, including oxygen reduction reaction kinetics, mass-transport processes, and electrolyte resistance loss [3]. EIS has been an increasingly popular diagnostic technique at the SOFC single cell level but has so far only seen limited use on the stack level [4–7].

One of the key challenges in associated with impedance measurements of large area objects, such as the experimental SOFC stack considered here, is that the absolute real impedance for a cell in the experimental stack is in the range of a few mΩ which requires equipment with high precision and minimisation of unwanted stray impedances in the geometrical set-up. Stray impedances are caused by mutual inductance and stray capacitance and do not describe the fuel cell. Three different stack geometries were investigated by electrochemical impedance spectroscopy for stray impedance minimisation. Furthermore active electrical circuits were attached the measurement input in order to ensure the highest measurement resolution of the frequency response analyser.

In the present work, the durability of an experimental 13-cell stack, in which the metallic interconnects were coated with different types of protective layers, has been tested for more than 2500 hours at steady operating conditions. EIS has been used to examine the long-term behaviour and monitor the evolution of series and polarisation resistances for four out of the 13 cells. The losses for the four cells are reported and discussed.

2. Experiments

The solid oxide fuel cells (SOFC) used for the 13-cell experimental fuel cell stack were planar anode-supported SOFCs (Ni-YSZ/YSZ/LSM-YSZ) of 12 cm x 12 cm footprint and an active area of approximately 90 cm². The cell details can be found elsewhere [8]. The interconnects were made of commercial stainless steel. Different coatings was used on the interconnects in the stack (see Table 1) to prevent chromium poisoning on the cathode side [9]. The nickel oxide in the Ni-YSZ electrode was reduced to nickel in hydrogen at start-up and the stack was subsequently tested for performance and durability. The stack testing was performed at DTU Energy Conversion with an experimental stack manufactured by Topsoe Fuel Cell A/S (TOFC).
An investigation of the optimal geometrical placement of the current probes and voltage probes was carried out in order to minimise measurement errors caused by stray impedances. Unwanted stray impedances are particularly problematic at high frequencies. The optimal stack geometry was found by performing EIS on three different stacks. The three different stack geometries are shown in Figure 1. For configuration A there was big difference in the high frequency response between the different cells in the stack since the magnetic field from the current conduction was influencing the voltage probes and causing a greater measurement error (greater stray impedance). Configuration B improved the high frequency response, but there was still a large deviation in the high frequency response between different cells in the stack. In configuration C the current conduction (out of the plane) was perpendicular to the voltage probes to minimise stray impedances as much as possible. This gave a consistent high frequency response between the different cells and decreased stray impedances. The experimental stack was therefore assembled with configuration C.

The stack was sealed along the edges with a glass seal designed by TOFC. The fuel cell stack can be considered to consist of a number of repeating units (RU). Each repeating unit contains interconnects, glass seals and a cell. A schematic representation of the experimental stack is shown in Figure 2.
The stack was tested using an automated test rig purchased from a commercial supplier. The stack was characterised using Electrochemical Impedance Spectroscopy (EIS). An illustration of the impedance custom test set-up is shown in figure 2. The EIS computer controls the Solartron 1260 Frequency Response Analyzer (FRA), via a GPIB communication bus. The Solartron 1260 sends an AC voltage signal from the generator output to the programmable input (Prg. Input) of a Kepco Bipolar Operational Amplifier 20-20D (Kepco Op-Amp). The Kepco Op-Amp converts the AC voltage signal to a corresponding AC current signal with a current-to-voltage ratio of 1 A/V. The generated AC current through the SOFC stack is superimposed on the DC current provided by the Electronic load of the test stand. Four terminal measurements were used to measure the (time-dependent) currents and voltages of the RUs. The voltage of a RU was measured by a differential probe connected to the differential input V1 on the Solartron 1260. The current through the stack was measured with an active current transducer (LEM ITN-600) which has a linear response up to 200 kHz. The DC voltage and the common mode voltage was minimised by additional active electrical circuits in order to utilise the highest measurement resolution on the Solartron.

EIS spectra were recorded from 97 kHz to 0.3 Hz with an ac current modulation of 0.8 A at OCV or on top of the nominal dc current of 18.5 A during the galvanostatic long term degradation test. The AC current amplitude was selected by testing four different current amplitudes (0.25A, 0.5A, 1A and 3A). The linear Kramers-Kronig transform test was used for immittance data validation producing residuals within a range of ±2% and a $\chi^2$ in the range of $9.1 \times 10^{-5}$ to $10 \times 10^{-5}$ [10].
Before the long term degradation test the stack was characterised with fuel consisting of H$_2$ with 20% H$_2$O at 700, 750 and 800°C in order to establish the temperature dependence of the losses in the stack. Temperature monitoring was performed with type S (Pt/Pt-Rh) thermocouples for the fuel and oxidant inlet at the top and bottom end-plates. The long term degradation test was carried out at constant current (galvanostatic) conditions at 0.2 A cm$^{-2}$ (18.5 A) and the stack temperature set to 750°C. The fuel was H$_2$ with 4% H$_2$O the oxidant was air. After 200 h, 4% H$_2$O was added to the air. The fuel and oxygen utilisation was 52% and 19%, respectively.

3. Results

3.1 Initial performance
Figure 4 shows the initial performance and scattering in resistance of the different cells in the stack measured by EIS. The series resistance, $R_s$ and the polarisation resistance $R_p$ are derived from the EIS data and the cells are grouped in colours which represent the different coatings. The $R_s$ and $R_p$ data presented here were extracted from the real part of the impedance at the highest and lowest frequency. The RUs with the standard ceramic coat has the lowest total resistance, yields the lowest $R_p$ values, and also exhibits among the smallest cell-to-cell variations. The RUs with Cu LSM wet spray coating (cells 5 and 11) has a low $R_s$ value but a high $R_p$ value. The large scatter in $R_s$ and $R_p$ values for the different cells is likely due to that the stack is an experimental stack optimised for electrochemical impedance spectroscopy, which in this case resulted in a different pressure (compressive force) distribution compared to a standard stack.

Due to the time-consuming nature of the impedance characterisation carried out, not helped by the largely manual multiplexing between cells, four cells were selected for detailed analysis impedance analysis and degradation mode tracking. The cells (#2,4,6,11) were selected based on physical placement in the stack, and on the interconnect coating material. The temperature dependence in $R_s$ and $R_p$ for the four cells...
A plot of interest is shown in Figure 5. The corresponding activation energies for $R_s$ and $R_p$ are shown in Table 2.

### 3.2 Long term degradation behaviour

The cell voltage history plot in Figure 6 shows the average cell voltage for the stack RUs. It can be split into four periods divided by shorter periods in which the data-logging system was off-line. In the middle of degradation period 1 the air humidification was initiated. The galvanostatic test was continuous however, also in periods without data-logging. The average degradation rate is not constant during the test, but is greatest in period 1. When examining individual cell voltages (Figure 7), it is clear that RUs with different coating materials display very different degradation behaviour. In period 2 the degradation rate vary from cell 2 with -4.5 mV·kh$^{-1}$ to cell 6 with -18.4 mV·kh$^{-1}$. In period 4 the degradation rate vary from cell 2 with -1.1 mV·kh$^{-1}$ to cell 11 with -84.2 mV·kh$^{-1}$. Cell 11 displays a progressive degradation trend (accelerating degradation) [11]. This may be due to effects such as spallation of the coating and/or loss of contact between cell and interconnects, leading to hot-spots and increased corrosion, which accelerates the degradation further. The RU with the standard ceramic coat (cell 2) displays a linear degradation in periods 2-4 after the initial nonlinear voltage drop in period 1.
3.2.1 EIS monitoring

EIS spectra were recorded regularly on the four selected cells. Figure 8 shows EIS spectra of the four cells just after the air humidification was initiated. The absolute value for $R_s$ for the displayed impedance spectra is in the range between 5 to 8 mΩ.

Figure 9 shows the resistance behaviour versus time for the series resistance, $R_s$, and the polarisation resistance, $R_p$, as measured under current.
3.2.2 Degradation mode tracking

Figure 10 shows the normalised polarisation resistance, $R_p^0/R_p$ versus normalised series resistance, $R_s^0/R_s$ where point (1,1) correspond to the initial situation. Plotting the evolution of normalised series and polarisation resistance starting at (1,1) provides useful visual information about the nature and extent of degradation. A degradation mode that mainly affects $R_s$ like oxide layer growth appears as an almost horizontal progressing leftward with increasing extent of degradation [12]. Nickel coarsening (at shorter time-scales) [13], chromium poisoning [14] and/or water induced changes on the cathode side [15], is reflected as a vertical line down from (1,1) since it is mainly affects the $R_p$. If the normalised resistance trajectory follows the 45 degree line it is an indication that a degradation process that changes the active area of the cell (e.g. delamination) may be dominating the degradation [12]. It is important to note that this way of plotting do not identify the degradation specifically, it only aids in identifying main types of degradation, $R_s$ only, $R_p$ only or usually both in various proportions.

Figure 10 illustrates that the degradation of cell 2 with the standard coating is characterised by occurring at the same rate for both $R_s$ and $R_p$ which could indicate a mechanism that changes the active area of the cell. For cell 4 one also observes that both resistances increase, but here $R_s$ increases at a faster rate than $R_p$ – this could indicate a combination of change the active area of the cell and an “$R_s$-only process” like e.g. oxide layer growth. Cell 6 and cell 11 behave differently; for these cells $R_s$ decreases over time, but $R_p$, which dominate the total resistance increases. Figure 10 show the relative changes for $R_s$ and $R_p$. For absolute changes of $R_s$ and $R_p$ see Figure 9.

4. Conclusions

A 13-cell experimental SOFC stack was tested during 2,500 hours of continuous operation with hydrogen as fuel with 52% fuel utilisation and constant current load (0.2 A cm\(^{-2}\)) at 750°C. Stack interconnects was coated with six different coatings to prevent chromium poisoning on the cathode side.

The stack geometry, in terms of current path and voltage probe placement was optimised for electrochemical impedance spectroscopy (EIS). The results illustrate that detailed EIS is possible on large area stacks and a de-convolution of the total loss into an ohmic and a non-ohmic part can be made.

The linear Kramers-Kronig Transform was used for data validation of the impedance spectra. Four cells were selected for detailed impedance analysis and degradation mode tracking. Cell 2 with the standard ceramic coating displayed the lowest long term degradation. The degradation of cell 4 with Co LSM wet sprayed coating was dominated by an increase of the series resistance with time, which could indicate that oxide layer growth was relatively rapid in the RU. Cell 6 and cell 11 showed increasing Rp values but decreasing Rs values. Analysis of all cell impedances in the stack (carried out at specific times only) show that the difference in behaviour between the four RU’s does lie in the different interconnect coatings. Whereas the performance of the experimental coatings is unsatisfactory the experiment is successful in terms of characterisation – the EIS allowed a distinction to be made in terms of the degradation between the four RU types that is not possible from IV-data only.
