** Introduction 

Silver is the most common material in commercial products integrating some form of nanotechnology. It is mostly used for its antimicrobial and antibacterial properties.

Increasingly popular, silver nanoparticles (AgNPs) are more and more likely to be released to the aquatic environment during the manufacturing, use or waste lifecycle stages of nanoproducts.

However, still little is currently known on the toxicity of AgNPs and the mechanisms of their toxicity.

The aim of this study was to evaluate how nanoparticle properties and water medium parameters influence the toxicity of silver nanoparticles and whether changes in toxicity could be explained using conceptual models such as the Biotic Ligand Model.

** Results 

Concentration–response curves for the silver compounds (excluding AgNP+MUDA) in closed tests at pH 7

Concentration–response curves for the silver compounds (excluding AgNP+MUDA) in closed tests at pH 8

EC50-48h (µgAg/L) of silver compounds in closed tests at pH 7 and 8.

AgNP+MUDA showed no significant toxicity under 1 mgAg/L.

AgNO3 algal growth inhibition in closed tests at pH 8 with cation additions.

** Outlook – A new approach to testing NPs? 

The sensitivity of an alternative short-term (2h) algal test, using C-14 incorporation as endpoint was studied.

This 2h test was found to be as sensitive as the standard (ISO) test, when testing the toxicity of Ag+ (AgNO3). Statistically similar EC50 values were obtained using the two methods (closed test pH 7).

Besides from being fast, easy and efficient - this test method may also circumvent the challenges related to the instability of nanoparticles in solution. Minimizing exposure time is expected to minimize the effects of time-dependent processes such as aggregation, sedimentation, ion release and interactions between NPs and media components/test organisms – suspected contributors to the poor reproducibility in nanoecotoxicology.

Further research will assess the appropriateness of this method.

** Conclusions 

• Concentration–response curves could be built for AgNP+Citrate and NM-300K, whereas AgNP+MUDA did not exhibit any significant toxicity in the tested concentration ranges.

• AgNPs were consistently less toxic than AgNO3 based on total silver concentrations.

• All silver compounds (except AgNP+MUDA) showed a decrease in toxicity from pH 8 to 7, in accordance with the Biotic Ligand Model.

• This could not be reproduced with competing cation additions, possibly because of the low concentrations used. Li+ addition may create a combination effect with silver nitrate, actually increasing the toxicity.

• A 2h algal test with AgNO3 had the same sensitivity as the standard ISO test - and may circumvent some of the challenges related to ecotoxicological testing of nanoparticles.
