ABSTRACT
This technical note documents the equations for primal-dual interior-point quadratic programming problem solver used for MPC. The algorithm exploits the special structure of the MPC problem and is able to reduce the computational burden such that the computational burden scales with prediction horizon length in a linear way rather than cubic, which would be the case if the structure was not exploited. It is also shown how models used for design of model-based controllers, e.g. linear quadratic and model predictive, can be linearized both at equilibrium and non-equilibrium points, making the presented extension of the controller formulation equivalent to that of the extended Kalman filter compared to an ordinary Kalman filter.

KEYWORDS
linear quadratic control, model predictive control, primal-dual interior-point quadratic programming problem

1 Introduction
State-space control methods based on linear models such as linear quadratic control (LQ), model predictive control (MPC) etc. are typically based on linearizations around equilibrium points, where the control objectives seek to minimize the distance from the current point of operation to the equilibrium point. Gain scheduling frameworks for different operating conditions can be used to handle nonlinearities. The classical gain scheduling framework, consisting of a Jacobian linearization family as described by Rugh and Shamma \cite{1}, is comprised of a family of linearizations all done at equilibrium points depending on the chosen scheduling variable. The mentioned control methods all have the same shortcoming, linearizations around equilibrium points are not guaranteed to resemble the actual dynamics at the current operating point. More advanced gain scheduling methods such as linear parameter varying (LPV) methods enable linearizations within a finite parameter space and are not limited to a set of equilibrium points. With an increasing number of scheduling variables and with an increasing discretization of the scheduling variables, the dimensions of the parameter space quickly grows and renders the practical implementation close to impossible, especially if constraints on states, outputs and inputs are to be handled by the controller. The easy fix to avoid the explosion of dimensions in the parameter space is to re-linearize the model online at each sample time and design a controller based on the linearized model, taking non-equilibrium residuals of the linearization into account in the controller design. No theoretical guarantees concerning stability etc. can however be given to this ad-hoc procedure compared to the theoretically better founded LPV framework.

If one or more outputs are to be steered towards their desired reference values several methods exits: The first is to augment the system with an integrator for each reference tracked output and seek to minimize the integrated the error between the output and the reference value. For varying reference values or constraints on e.g. control signals or control signal rates, integrator wind-up can occur, giving rise to unwanted overshoot performance of the closed-loop. A second option is to use target calculation to determine the new steady state target values for states and control signals and use an origin-shifting controller framework, e.g. as proposed by Pannocchia and Rawlings \cite{2}.
In this note, it is shown how to gather reference tracking and relinearization at non-stationary points, into a unified formulation, which serves as an extension to the standard Linear Quadratic (LQ) formulation. Model Predictive Control (MPC) with quadratic cost functions is similar to the standard LQ control and the unified control formulation can be applied to MPC as well. Rao et al. [3] has shown how to ease the computational burden of MPC by exploiting the structure given by an inequality constrained optimal control problem. The method suggested by Rao et al. [3] is extended to accommodate the unified formulation presented in this paper. Similar algorithms exploiting the structure of the interior-point optimization problem have subsequently been implemented by others, e.g. Edlund et al. [4] and Haverbeke et al. [5] for MPC and Moving Horizon Estimation purposes, respectively. The extended MPC formulation is also able to act as the quadratic programming problem (QP) solving algorithm used by a sequential quadratic programming solver, when applied to Nonlinear Model Predictive Control (NMPC) as done by Tenny et al. [6].

This document's outline is: In the first section unconstrained MPC and reference-tracking non-stationary LQ control is presented. In the second section it is shown how to exploit the structure of an inequality constrained MPC adapted to the unified control framework when solving the QP. To relate the second section to a quadratic programming problem solver, theory for a general purpose primal-dual interior-point quadratic programming is revisited in the third section. In the last section it is shown how to obtain time discrete dynamic models at non-stationary points.

2 Unconstrained linear model predictive control

The finite horizon optimal control problem is given as

$$\min \phi_N(x_N) + \sum_{k=0}^{N-1} \phi_k(x_k, u_k)$$

where the stagewise cost function

$$\phi_k(x_k, u_k) = \frac{1}{2} \|r - g_r(x_k, u_k)\|_{W_r}^2 + \frac{1}{2} \|g_z(x_k, u_k)\|_{W_z}^2$$

consist of two terms: The first term seeks to drive the plant reference outputs $g_r(\cdot)$ towards the desired reference $r$. The second term seeks to minimize dynamic variations given by $g_z(\cdot)$ such as e.g. velocities, accelerations. The optimization problem is subject to an initial constraint

$$x_0 = \bar{x}$$

and to the nonlinear state progress equation constraint

$$x_{k+1} = f(x_k, u_k), \text{ for } k = 0, \ldots, N - 1$$

The nonlinear equations can be assumed linear throughout the entire prediction horizon to ease the problem solving. The state progress equation as well as the equations for the reference outputs $g_r(\cdot)$ and the dynamic outputs $g_z(\cdot)$ are linearized around $(\bar{x}, \bar{u})$

$$f(x_k, u_k) \approx Ax_k + Bu_k + \delta$$

$$g_r(x_k, u_k) \approx C_r x_k + D_r u_k + \gamma_r$$

$$g_z(x_k, u_k) \approx C_z x_k + D_z u_k + \gamma_z$$

The linearized stagewise cost function can be put on a more general form

$$\phi_k(x_k, u_k) = \frac{1}{2}(x_k^T Q x_k + u_k^T R u_k + 2x_k^T M u_k + 2q^T x_k + 2r^T u_k)$$
where
\[ Q = C_r^T W_r C_r + C_z^T W_z C_z \]  \hspace{2cm} (4a)
\[ R = D_r^T W_r D_r + D_z^T W_z D_z \]  \hspace{2cm} (4b)
\[ M = C_r^T W_r K_r + C_z^T W_z D_z \]  \hspace{2cm} (4c)
\[ q^T = [\gamma_r - r]^T W_r C_r + \gamma_z^T W_z C_z \]  \hspace{2cm} (4d)
\[ r^T = [\gamma_r - r]^T W_r D_r + \gamma_z^T W_z D_z \]  \hspace{2cm} (4e)

and the final state cost
\[ \phi_N(x_N) = \frac{1}{2} (x_N^T \Pi_N x_N + 2\pi_N x_N) \]  \hspace{2cm} (5)

The Lagrangian to optimal control problem is

\[ \mathcal{L} = \phi_N(x_N) + \sum_{k=0}^{N-1} \phi_k(x_k, u_k) + \nu_0^T (x_0 - x_0) + \sum_{k=0}^{N-1} \nu_{k+1}^T (A x_k + B u_k + \delta - x_{k+1}) \]  \hspace{2cm} (6)

The optimal solution is given by \( \nabla \mathcal{L} = 0 \), which can be found by a recursion of the stagewise Lagrangian gradients

\[ \nabla x_k \mathcal{L} = Q x_k + M u_k + q + A^T \nu_{k+1} - \nu_k \]  \hspace{2cm} (7)
\[ \nabla u_k \mathcal{L} = M^T x_k + R u_k + r + B^T \nu_{k+1} \]  \hspace{2cm} (8)

starting a the end of the prediction horizon

\[ \nabla x_N \mathcal{L} = \Pi_N + \pi_N - \nu_N \]  \hspace{2cm} (9)

inserting the final stage Lagrangian gradient (9) and the state progress equation (2a) into the \( N-1 \) stage Lagrangian gradient yields

\[ \nabla x_{N-1} \mathcal{L} = [Q_{N-1} + A^T \Pi_N A] x_{N-1} + \tilde{M}_{N-1} u_{N-1} + \tilde{q}_{N-1} - \nu_{N-1} \]  \hspace{2cm} (10)
\[ \nabla u_{N-1} \mathcal{L} = \tilde{M}_{N-1} x_{N-1} + \tilde{R}_{N-1} u_{N-1} + \tilde{r}_{N-1} \]  \hspace{2cm} (11)

where

\[ \tilde{R}_{N-1} = R + B^T \Pi_N B \]  \hspace{2cm} and \hspace{2cm} \[ \tilde{M}_{N-1} = M + A^T \Pi_N B \]  \hspace{2cm} (12)

and

\[ \tilde{q}_{N-1} = q + A^T \Pi_N \delta + A^T \pi_N \]  \hspace{2cm} and \hspace{2cm} \[ \tilde{r}_{N-1} = r + B^T \Pi_N \delta + B^T \pi_N \]  \hspace{2cm} (13)

are introduced to simplify notation. A control law can be derived from (11)

\[ u_{N-1} = -K_{N-1} x_{N-1} - \kappa_{N-1} \]  \hspace{2cm} (14)

where

\[ K_{N-1} = \tilde{R}_{N-1}^{-1} \tilde{M}_{N-1}^T \]  \hspace{2cm} and \hspace{2cm} \[ \kappa_{N-1} = \tilde{R}_{N-1}^{-1} \tilde{r}_{N-1} \]  \hspace{2cm} (15)

which can be inserted into (10) giving

\[ \nabla x_{N-1} \mathcal{L} = \Pi_{N-1} + \pi_{N-1} - \nu_{N-1} \]  \hspace{2cm} (16)

where

\[ \Pi_{N-1} = Q + A^T \Pi_N A - \tilde{M}_{N-1} K_{N-1} \]  \hspace{2cm} and \hspace{2cm} \[ \pi_{N-1} = \tilde{q}_{N-1} - \tilde{M}_{N-1} \kappa_{N-1} \]  \hspace{2cm} (17)
The recursion can then be continued for the stages \( N - 2, N - 3 \) etc. until the beginning of the prediction horizon. The variables can be reconstructed, if needed, with a forward recursion initiated with

\[
\bar{x} = x_0 \\
\nu_0 = \Pi_0 x_0 + \pi_0
\]

and then going from \( k = 0, \ldots, N - 1 \) where

\[
u_k = \bar{x}_k x_k - \kappa_k
\]

\[
x_{k+1} = A x_k + B u_k + \delta
\]

\[
u_{k+1} = \Pi_{k+1} x_{k+1} + \pi_{k+1}
\]

For a LTI system and \( N \to \infty \) the solution becomes an algebraic set of equations. The quadratic cost for the terminal cost is found by the discrete-time algebraic Riccati equation (DARE)

\[
\Pi = Q + A^T \Pi A - \tilde{M} K
\]

where to simplify notation, the matrices \( \tilde{M} = M + A^T \Pi B \) and \( \tilde{R} = R + B^T \Pi B \) are introduced, leading to the feedback gain \( K = \tilde{R}^{-1} \tilde{M}^T \). The linear terminal cost term \( \pi \) is determined from the same recursion as the DARE

\[
\pi = q - \tilde{M} \kappa + A^T \Pi \delta + A^T \pi
\]

where the control action contribution \( \kappa \)

\[
\kappa = \tilde{R}^{-1} [r + B^T \Pi \delta + B^T \pi]
\]

is part of the optimal control law

\[
u_k = -K x_k - \kappa
\]

The DARE should be solved using a specialized DARE solver [7] to achieve fast and robust results and the linear cost term can be found from (24)

\[
\pi = [I - A^T + K^T B^T]^{-1} [q - K^T [r + B^T \Pi \delta + A^T \Pi \delta] + A^T \Pi \delta]
\]

3 Inequality constrained MPC

In this section, the temporal subscript \( k \) has been omitted for the Jacobians \( A, B \) etc. even though that they can vary within the prediction horizon, if used within a NMPC framework. This is done to ease notation and because they remain constant within the iterations of the QP solver.

The model predictive controller entails the computation of the control signal within a prediction horizon in the range \( k = 0, \ldots, N - 1 \). The MPC is formulated as a dual mode horizon where the first part, i.e \( k = 0, \ldots, N - 1 \), is considered constrained. In the second horizon, i.e. \( k = (N + 1, \ldots, \infty) \), it is assumed that the plant has reached a state where the unconstrained solution is feasible [8]. The dual mode optimization problem is

\[
\min \sum_{k=0}^{N-1} \phi_k(x_k, u_k) + \sum_{k=1}^{N-1} \|\sigma_k\|^2_{W_x} + \sum_{k=N}^{\infty} \phi_k(x_k, u_k)
\]

where the stagewise cost function is \( \phi_k(\cdot) \) is given by (1b). The term \( \|\sigma_k\|^2_{W_x} \) is only included in the first part of the prediction horizon and seeks to minimize the violation of the soft constraints \( \sigma \). The optimization problem is subject to an initial constraint as in (1c) and to the state progress
equation (2a) in the interval \((k = 0, \ldots, \infty)\). Whereas the soft and hard inequality constraints are only active in the first part of the prediction horizon

\[
g_s(x_k) - \sigma_k \approx C_s x_k + \gamma_s - \sigma_k \leq s, \quad k = (1, \ldots, N - 1) \tag{28b}
\]

\[
\sigma_k \geq 0, \quad k = (1, \ldots, N - 1) \tag{28c}
\]

\[
g_h(x_k, u_k) \approx C_h x_k + D_h u_k + \gamma_h \leq h, \quad k = (0, \ldots, N - 1) \tag{28d}
\]

The constants contributions and the inequality limits can be combined in a redefined inequality limit to ease notation

\[
\bar{s} \equiv s - \gamma_s \quad \text{and} \quad \bar{h} \equiv h - \gamma_h
\]

The second part of the optimization problem can be reduced to a terminal cost, consisting of a quadratic \(\Pi_N\) and a linear term \(\pi_N\)

\[
\phi_N(x_N) = \sum_{k=N}^{\infty} \phi_k(x_k, u_k) = x_N^T \Pi_N x_N + \pi_N^T x_N \tag{29}
\]

given by the unconstrained DARE (23) and (27). The Lagrangian for the inequality constrained problem can written as

\[
\mathcal{L} = \phi_N(x_N) + \sum_{k=0}^{N-1} \phi_k(x_k, u_k) + \sum_{k=1}^{N-1} \|\sigma_k\|_W^2
\]

\[
+ \nu_0^T (\bar{x} - x_0) + \sum_{k=0}^{N-1} \nu_{k+1}^T (A x_k + B u_k + \bar{\delta} - x_{k+1})
\]

\[
+ \sum_{k=0}^{N-1} (\langle \lambda_h^k \rangle (C_h x_k + D_h u_k - \bar{h}) + \sum_{k=1}^{N-1} (\langle \lambda_s^k \rangle (C_s x_k - \bar{s} - \bar{s})) + \sum_{k=1}^{N-1} (\langle \lambda_e^k \rangle (-\sigma_k))
\]

\[
+ \sum_{k=0}^{N-1} \left( (\lambda_h^k)^T (C_h x_k + D_h u_k - \bar{h}) \right) + \sum_{k=1}^{N-1} \left( (\lambda_s^k)^T (C_s x_k - \bar{s}) \right) + \sum_{k=1}^{N-1} \left( (\lambda_e^k)^T (-\sigma_k) \right)
\]

where \(\nu_0\) is Lagrange multiplier for (1c); \(\nu_k\) for \(k = 1, \ldots, N\) is the Lagrange multiplier for (2a); \(\lambda_h^k, \lambda_s^k, \lambda_e^k\) are the Lagrange multipliers for (28d),(28b) and (28c) respectively.

The Karush-Kuhn-Tucker (KKT) conditions for optimality are

\[
\nabla \mathcal{L} = 0 \tag{31}
\]

\[
\bar{x} - x_0 = 0 \tag{32}
\]

\[
A x_k + B u_k + \bar{\delta} - x_{k+1} = 0 \tag{33}
\]

\[
C_h x_k + D_h u_k - \bar{h} \leq 0 \tag{34}
\]

\[
C_s x_k - \sigma_k - \bar{s} \leq 0 \tag{35}
\]

\[
-\sigma_k \leq 0 \tag{36}
\]

\[
\text{diag}(\lambda_h^k) \text{diag}(C_h x_k + D_h u_k - \bar{h}) e = 0 \tag{37}
\]

\[
\text{diag}(\lambda_s^k) \text{diag}(C_s x_k - \sigma_k - \bar{s}) e = 0 \tag{38}
\]

\[
\text{diag}(\lambda_e^k) \text{diag}(-\sigma_k) e = 0 \tag{39}
\]

\[
(\lambda_h^k, \lambda_s^k, \lambda_e^k) \geq 0 \tag{40}
\]

where (37), (38) and (39) are the complementary slackness conditions. By the introduction of the slack variables \(t_h^k, t_s^k\) and \(t_e^k\) for \(\lambda_h^k, \lambda_s^k\) and \(\lambda_e^k\) respectively, the KKT condition can be rewritten
where there appropriate ranges of \( k \) are omitted for ease of notation. \( T^h_k \equiv \text{diag}(t^h_k), A^h_k \equiv \text{diag}(\lambda^h_k), A^e_k \equiv \text{diag}(\lambda^e_k) \) and \( e = [1 \ 1 \ldots \ 1]^T \). The Jacobian of the Lagrangian \( \nabla L \) consist of

\[
\begin{align*}
\nabla x_k L &= Q x_k + M u_k + q_k - \nu_k + A^T \nu_{k+1} + C^T h \lambda^h_k \\
\nabla x_{\nu_k} L &= Q \ n x_k + M u_k + q_k - \nu_k + A^T \nu_{k+1} + C^T h \lambda^h_k + C^T e \lambda^e_k + q_k \\
\nabla u_k L &= R u_k + M^T x_k + r_k + B^T \nu_{k+1} + D^T h \lambda^h_k \\
\nabla \sigma_k L &= Z \sigma_k + z - \lambda^e_k - \lambda^e_k 
\end{align*}
\]

The Newton like step

\[
\nabla F \Delta w = - F = r 
\]

will be used to iterate towards a solution. The full KKT matrix \( \nabla F \) multiplied with the variable step \( \Delta w = [\Delta x_0 \ \Delta u_0 \ldots] \) and the residual vector \( r = [r^x_0 \ r^u_0 \ldots] \) are

\[
\nabla F \Delta w = 
\begin{bmatrix}
Q \Delta x_0 + M \Delta u_0 - \Delta \nu_0 + A^T \Delta \nu_1 + C^T h \Delta \lambda^h_k \\
Q \Delta x_k + M \Delta u_k - \Delta \nu_k + A^T \Delta \nu_{k+1} + C^T h \Delta \lambda^h_k + C^T e \Delta \lambda^e_k + q_k \\
\Pi_N \Delta x_N - \Delta \nu_N \\
R \Delta u_k + M^T \Delta x_k + B^T \Delta \nu_{k+1} + D^T h \Delta \lambda^h_k \\
Z \Delta \sigma_k - \Delta \lambda^e_k - \Delta \lambda^e_k \\
-\Delta x_0 \\
A \Delta x_k + B \Delta u_k - \Delta x_{k+1} \\
D_h \Delta u_k + C_h \Delta x_k + \Delta t^h_k \\
C_a \Delta x_k - \Delta \sigma_k + \Delta t^e_k \\
-\Delta \sigma_k + \Delta t^e_k \\
T^h_k \Delta \lambda^h_k + A^h_k \Delta t^h_k \\
T^e_k \Delta \lambda^e_k + A^e_k \Delta t^e_k \\
T^\sigma_e \Delta \lambda^e_k + A^\sigma_e \Delta t^\sigma_k
\end{bmatrix} 
\]

(42)
where $\Omega_h = \text{diag}(\Delta t^h)\text{diag}(\Delta \lambda^h) - \sigma \mu$, $\Omega_s = \text{diag}(\Delta t^s)\text{diag}(\Delta \lambda^s) - \sigma \mu$ and $\Omega_\sigma = \text{diag}(\Delta t^\sigma)\text{diag}(\Delta \lambda^\sigma) - \sigma \mu$ are the centering terms for the corrector step in the predictor-corrector algorithm.

The slack variables $\Delta t^h$, $\Delta t^s$ and $\Delta \lambda^k$ are eliminated using $\Delta t^h = (A^h)^{-1}(r^z - T^h_k \Delta \lambda^h_k)$, $\Delta t^s = (A^s)^{-1}(r^z - T^s_k \Delta \lambda^s_k)$ and $\Delta \lambda^k = (A^\sigma)^{-1}(r^z - T^\sigma_k \Delta \lambda^\sigma_k)$ respectively, giving

$$\nabla F \Delta w = \begin{bmatrix} Q\Delta x_0 + M\Delta u_0 - \Delta \nu_0 + \Delta^T \nu_1 + C_{\delta}^T \Delta \lambda^h_0 \\ Q\Delta x_k + M\Delta u_k - \Delta \nu_k + \Delta^T \nu_{k+1} + C_{\delta}^T \Delta \lambda^h_k \\ \Pi_N \Delta x_N - \Delta \nu_N \\ R\Delta u_k + M^T \Delta x_k + B^T \Delta \nu_{k+1} + D_{\delta}^T \Delta \lambda^h_k \\ Z\Delta \sigma_k - \Delta \lambda^s_k - \Delta \lambda^\sigma_k \\ -\Delta x_0 \\ A\Delta x_k + B\Delta u_k - \Delta x_{k+1} \\ D_h\Delta u_k + C_h\Delta x_k - \Sigma^h_k \Delta \lambda^h_k \\ C_s\Delta x_k - \Delta \sigma_k - \Sigma^s_k \Delta \lambda^s_k \\ -\Delta \sigma_k - \Sigma^\sigma_k \Delta \lambda^\sigma_k \end{bmatrix}$$

where $\Sigma^h_k = (A^h_k)^{-1}T^h_k$, $\Sigma^s_k = (A^s_k)^{-1}T^s_k$ and $\Sigma^\sigma_k = (A^\sigma_k)^{-1}T^\sigma_k$

$$\begin{bmatrix} r^z_0 \\ r^z_k \\ r^z_N \\ r^z_{k+1} \\ r^\lambda^h_k \\ r^\lambda^s_k \\ r^\lambda^\sigma_k \end{bmatrix} = \begin{bmatrix} r^z_0 \\ r^z_k \\ r^z_N \\ r^z_{k+1} \\ r^\lambda^h_k - (A^h_k)^{-1}r^\lambda^h_k \\ r^\lambda^s_k - (A^s_k)^{-1}r^\lambda^s_k \\ r^\lambda^\sigma_k - (A^\sigma_k)^{-1}r^\lambda^\sigma_k \end{bmatrix}$$

Eliminating $\Delta \lambda^h_k$, $\Delta \lambda^s_k$ and $\Delta \lambda^\sigma_k$ (using $\Delta \lambda^h_k = (\Sigma^h_k)^{-1}(D_h\Delta u_k + C_h\Delta x_k - r^\lambda^h_k)$, $\Delta \lambda^s_k = (\Sigma^s_k)^{-1}(C_s\Delta x_k - \Delta \sigma_k - r^\lambda^s_k)$ and $\Delta \lambda^\sigma_k = (\Sigma^\sigma_k)^{-1}(-\Delta \sigma_k - r^\lambda^\sigma_k)$), and afterwards eliminating $\Delta \sigma_k$ (using $\Delta \sigma_k = Z^{-1}(C_{\delta}^T(\Sigma^h_k)^{-1}\Delta x_k + r^\sigma_k)$) where $r^\sigma_k = r^\sigma_k - (\Sigma^\sigma_k)^{-1}r^\lambda^\sigma_k - (\Sigma^\sigma_k)^{-1}r^\lambda^\sigma_k$ yields

$$\nabla F \Delta w = \begin{bmatrix} Q_0 \Delta x_0 + M_0 \Delta u_0 - \Delta \nu_0 + \Delta^T \nu_1 \\ Q_k \Delta x_k + M_k \Delta u_k - \Delta \nu_k + \Delta^T \nu_{k+1} \\ \Pi_N \Delta x_N - \Delta \nu_N \\ R_k \Delta u_k + M_f^T \Delta x_k + B^T \Delta \nu_{k+1} \\ -\Delta x_0 \\ A\Delta x_k + B\Delta u_k - \Delta x_{k+1} \end{bmatrix}$$
and the residuals
\[
\begin{bmatrix}
 r_0^e \\
r_k^e \\
r_N^e \\
r_k^u \\
r_0^u \\
r_{k+1}^u \\
\end{bmatrix} =
\begin{bmatrix}
 r_0^e + C_k^T (\Sigma_k^H)^{-1} r_k^h \\
r_k^e + C_k^T (\Sigma_k^H)^{-1} r_k^h + C_k^T (\Sigma_k^H)^{-1} \bar{z}_k^{-1} r_k^e \\
r_N^e + D_k^T (\Sigma_k^H)^{-1} r_k^h \\
r_k^u \\
r_0^u \\
r_{k+1}^u \\
\end{bmatrix}
\]
(54)

where
\[
\bar{R}_k = R + D_h^T (\Sigma_k^H)^{-1} D_h \\
\bar{M}_k = M + C_h^T (\Sigma_k^H)^{-1} D_h \\
\bar{Z}_k = Z + (\Sigma_k^H)^{-1} + (\Sigma_k^H)^{-1} \\
Q_0 = Q + C_h^T (\Sigma_k^H)^{-1} C_h \\
\]

where
\[
\bar{R}_{N-1} = [\bar{R}_{N-1} + B^T \Pi_N B] \\
\bar{M}_{N-1} = [\bar{M}_{N-1} + A^T \Pi_N B] \\
K_{N-1} = \bar{R}_{N-1}^{-1} \bar{M}_{N-1} \\
\Pi_{N-1} = \bar{Q}_{N-1} + A^T \Pi_N A - \bar{M}_{N-1} K_{N-1} \\
\kappa_{N-1} = \bar{R}_{N-1}^{-1} [\bar{r}_{N-1} + B^T \bar{r}_N + B^T \Pi_N r_{N-1}^u] \\
\pi_{N-1} = \bar{r}_{N-1}^p + A^T \Pi_N r_{N-1}^u + A \bar{r}_N^p - \bar{M}_{N-1} \kappa_{N-1}
\]
(61) (62) (63) (64) (65) (66)

The recursion can be continued for \( k = N - 1, \ldots, 0 \)
\[
\bar{R}_k = [\bar{R}_k + B^T \Pi_{k+1} B] \\
\bar{M}_k = [\bar{M}_k + A^T \Pi_{k+1} B] \\
K_k = \bar{R}_k^{-1} \bar{M}_k \\
\Pi_k = \bar{Q}_k + A^T \Pi_{k+1} A - \bar{M}_k K_k \\
\kappa_k = \bar{R}_k^{-1} [\bar{r}_k^p + B^T \bar{r}_N + B^T \Pi_N r_{k+1}^u] \\
\pi_k = \bar{r}_k^p + A^T \Pi_{k+1} r_{k+1}^u + A \bar{r}_N^p - \bar{M}_k \kappa_k
\]
(67) (68) (69) (70) (71) (72)

A forward recursion can be used to construct variables
\[
\Delta x_0 = -r_0^p \\
\Delta \nu_0 = \Pi_0 \Delta x_0 - \pi_0
\]
(73) (74)

For \( k = 0, \ldots, N - 1 \)
\[
\Delta u_k = -K_k \Delta x_k + \kappa_k \\
\Delta x_{k+1} = A \Delta x_k + B \Delta u_k - r_{k+1}^u \\
\Delta t_k^h = -D_h \Delta u_k - C_h \Delta x_k + r_k^h \\
\Delta \lambda_k^h = (T_k^h)^{-1} (t_k^h - \Lambda_k^h \Delta t_k^h)
\]
(75) (76) (77) (78)
For \( k = 1, \ldots, N - 1 \)

\[
\begin{align*}
\Delta \sigma_k &= \bar{Z}^{-1}(C_k^T (\Sigma_k^e)^{-1} \Delta x_k + \bar{r}_k^e) \\
\Delta \nu_k &= \Pi_k \Delta x_k - \pi_k \\
\Delta t^s_k &= -C_k \Delta x_k + \Delta \sigma_k + r_k^s \\
\Delta t^\nu_k &= \Delta \sigma_k + r_k^\nu \\
\Delta \lambda_k^s &= (T_k^s)^{-1}(r_k^s - \Lambda_k^s \Delta t^s_k) \\
\Delta \lambda_k^\nu &= (T_k^\nu)^{-1}(r_k^\nu - \Lambda_k^\nu \Delta t^\nu_k) \\
\end{align*}
\]

4 Linear constrained quadratic optimization

This section describes the underlying quadratic programming problem (QP) solver based on an interior-point primal-dual formulation. The algorithm (Alg. 1) is taken from Rao et al. [3], similar algorithms can be found in Wright [9] and Nocedal and Wright [10]. The mentioned algorithms are all based on the predictor-corrector method developed by Mehrotra [11]. The standard QP is given as

\[
\begin{align*}
\min_{x} & \quad \frac{1}{2}x^T Q x + c^T x \\
\text{subject to} & \quad Ax = b \\
& \quad Cx \leq d 
\end{align*}
\]  

(85a) \hspace{1cm} (85b) \hspace{1cm} (85c)

where the Hessian \( Q \) is a symmetric positive semidefinite matrix. The Lagrangian to (85) is

\[
\mathcal{L}(x, \lambda, \nu) = x^T Q x + c^T x + \lambda^T (C x - d) + \nu^T (A x - b)
\]  

(86)

Leading to the Karush-Kuhn-Tucker (KKT) conditions

\[
\begin{align*}
Q x + c + A^T \nu + C^T \lambda &= 0 \\
A x - b &= 0 \\
C x - d &\leq 0 \\
\lambda &\geq 0 \\
\lambda^T (C x - d)e &= 0 
\end{align*}
\]  

(87a) \hspace{1cm} (87b) \hspace{1cm} (87c) \hspace{1cm} (87d) \hspace{1cm} (87e)

where (87a) is the stationarity condition, (87b) and (87c) are the primal feasibility conditions, (87d) is the dual feasibility condition and (87e) is the complimentary slackness condition for the primal-dual problem. Introducing the slack variable \( t \) to (85c) simplifies the KKT conditions and gives the following system to solved

\[
\mathcal{F}(w) = \begin{bmatrix}
Q x + c + A^T \nu + C^T \lambda \\
A x - b \\
C x - d - t \\
\lambda^T T e
\end{bmatrix}
\]  

(88)

where \( \Lambda = \text{diag}(\lambda) \) and \( T = \text{diag}(t) \) , \( w = (x, \nu, \lambda, t) \). Newton like steps \( \nabla \mathcal{F} \Delta w = -\mathcal{F} = r \) can be taken to iterate towards the solution. Multiple methods exist but one the most used is the predictor-corrector method by Mehrotra [11]. The method starts with a predictor step

\[
\begin{bmatrix}
Q & A^T & C^T & 0 \\
A & 0 & 0 & 0 \\
C & 0 & 0 & -I \\
0 & 0 & T & \Lambda
\end{bmatrix}
\begin{bmatrix}
\Delta x^{off} \\
\Delta \nu^{off} \\
\Delta \lambda^{off} \\
\Delta t^{off}
\end{bmatrix}
= -\begin{bmatrix}
r^x \\
r^\nu \\
r^\lambda \\
r^t
\end{bmatrix}
\]  

(89)
where
\[
\begin{align*}
    r^x &= Qx + c - A^T \nu - C^T \lambda \
    r^\nu &= Ax - b \
    r^\lambda &= Cx - t - d \
    r^t &= \Lambda^T e
\end{align*}
\] (90)

The largest possible step size without violating the inequality constraints is calculated
\[
\alpha^{aff} = \arg \max \{ \alpha \in [0, 1] | (\lambda, s) + \alpha(\Delta \lambda^{aff}, \Delta s^{aff}) \geq 0 \} \] (94)

The current complementary measure
\[
\mu = \lambda^T s / \dim(\lambda) \] (95)

is a measure of the current feasibility and the affine complementary measure
\[
\mu^{aff} = (\lambda + \alpha^{aff} \Delta \lambda)^T (s + \alpha^{aff} \Delta s) / \dim(\lambda) \] (96)

is a measure of the feasibility if the full predictor step was taken. The predictor step is followed by a corrector step which takes the centering parameter into account
\[
\sigma = \left( \frac{\mu^{aff}}{\mu} \right)^3 \] (97)

to keep the iterate at the central path between the primal and the dual problem and thus away from infeasibility. This is done by modifying the residual \( r^t \) with the corrector term \( \Omega = \text{diag}(\Delta t^{aff}) \text{diag}(\Delta \lambda^{aff}) e - \sigma \mu e \)
\[
\begin{bmatrix}
    Q & A^T & C^T & 0 \\
    A & 0 & 0 & 0 \\
    C & 0 & 0 & -I \\
    0 & 0 & T & \Lambda
\end{bmatrix}
\begin{bmatrix}
    \Delta x \\
    \Delta \nu \\
    \Delta \lambda \\
    \Delta t
\end{bmatrix} = -
\begin{bmatrix}
    r^x \\
    r^\nu \\
    r^\lambda \\
    r^t + \Omega
\end{bmatrix} \] (98)

The corrected step size can then be calculated
\[
\alpha = \arg \max \{ \alpha \in [0, 1] | (\lambda, s) + \alpha(\Delta \lambda, \Delta s) \geq 0 \} \] (99)

and the variables can be updated
\[
w^{+} = w + \alpha \beta \Delta w, \quad 0 < \beta < 1 \] (100)

where \( \beta \) is a damping factor typically close to 1, this damping is imposed on the step to improve the numerical stability of the algorithm. Convergence is assumed if
\[
\mu \leq \text{tol}_\mu \quad \text{and} \quad ||r||_\infty \leq \text{tol}_r ||(Q, A, C, b, d)||_\infty \] (101)

Care should also be taken when determining an initial guess, see e.g. Mehrotra [11] to determine good starting points for \( \lambda \) and \( t \) such that they are sufficiently far away from infeasibility but at the same time not to far away from each other as convergence speed would be impaired otherwise.

## 5 Linearization of models

A dynamic system can be described by the differential state equation and an output equation
\[
\begin{align*}
    \dot{x}(t) &= f(x(t), u(t)) \tag{102a} \\
    y(t) &= g(x(t), u(t)) \tag{102b}
\end{align*}
\]
Algorithm 1: Interior-point primal-dual quadratic programming solver

Initial guess:
if Constraints are not violated then
  Return with result;
for ITER from 1 to IMAX do
  Solve $\nabla F \Delta w^{aff} = -r$;
  Calc. $\alpha^{aff} = \max \{ \alpha \in (0, 1] | \alpha(\Delta t^{aff}, \Delta \lambda^{aff}) \geq 0 \}$;
  Calc. $\mu = t^T \lambda / m$;
  Calc. $\mu^{aff} = (t + \alpha^{aff} \Delta t^{aff})^T (\lambda + \alpha^{aff} \Delta \lambda^{aff}) / m$;
  Calc. $\sigma = (\mu^{aff} / \mu)^3$;
  Calc. residuals with corrector terms: $r^{corr} = (r^x, r^u, r^\lambda, r^t + \Omega)$;
  Solve $\nabla F \Delta w = -r^{corr}$;
  Calc. $\alpha = \max \{ \alpha \in (0, 1] | \alpha(\Delta t, \Delta \lambda) \geq 0 \}$;
  Update variables: $w^{+} = w + \alpha \beta \Delta w$;
  Calc. residuals used by next predictor step: $r$;
if Convergence then
  Terminate algorithm;
endif

For the application of model predictive control several methods of time-discretization exits, for nonlinear model predictive control where the model is re-linearized at each temporal point in the prediction horizon, the time-discretization method influences the convergence properties of the NLP solver. Forward Euler time integration is probably the most simple choice. Runge-Kutta time integration schemes are common choices for time discretization of the models. The computation of the sensitivity/Jacobian matrices ($A$, $B$) of the state progress equation can be computationally expensive. Methods such as the one suggested by Kristensen et al. [12], seeks to minimize the computational burden by reusing already calculated information. Yet another time discretization method, which can be used for NMPC is collocation of time-discrete points [13], which shall not be discussed further in this work.

If the models can be assumed to be linear within a time step of the prediction horizon, the computational burden of time-integration might be reduced significantly. The differential state equation and the measured outputs are linearized around $(\bar{x}, \bar{u})$ using first order Taylor series approximation

\[
\begin{align*}
  f(x_k, u_k) &\approx Ax_k + Bu_k + \delta \\
  g(x_k, u_k) &\approx Cx_k + Du_k + \gamma
\end{align*}
\]

where the constant contributions $\delta$ and $\gamma$ are

\[
\begin{align*}
  \delta &= f(\bar{x}, \bar{u}) - A\bar{x} - B\bar{u} \\
  \gamma &= g(\bar{x}, \bar{u}) - C\bar{x} - D\bar{u}
\end{align*}
\]

The time-discrete state progress equation

\[
x_{k+1} = x_k + \int_{t_k}^{t_{k+1}} f(x(t), u(t))dt
\]

can, under the assumption of being linear and having a constant input $u$ within a time step, be time-discretized by the zero-order-hold method [14] and written as

\[
f(x_k, u_k) \approx x_k + \int_{t_k}^{t_{k+1}} Ax(t) + Bu(t)dt + \int_{t_k}^{t_{k+1}} \delta dt = Ax_k + Bu_k + \hat{\delta}
\]

where

\[
\hat{\delta} = \Delta t \delta
\]
and where

$$\begin{bmatrix} A & B \\ 0 & I \end{bmatrix} = \expm \left( \Delta t \begin{bmatrix} A & B \\ 0 & 0 \end{bmatrix} \right)$$  \hfill (109)$$

where \(\expm\) is the matrix exponential function, usually approximated by a Padé approximation with scaling and squaring [15]. Linear forward Euler time integration can be used instead of the zero-order-hold method. The time step \(\Delta t\) can be divided into \(n\) even smaller equidistant time steps and a forward recursion can calculate the state values at the next time step

$$x_{i+1} = x_i + \frac{\Delta t}{n} \dot{x}_i = x_i + \frac{\Delta t}{n} (Ax_i + Bu_i + \delta)$$  \hfill (110)$$

where \(i\) is the local time index between time \(t_k\) and \(t_{k+1}\). The time discrete state and input matrices \(A\) and \(B\) are initiated as

$$A = I \quad \text{and} \quad B = 0$$  \hfill (111)$$

and updated as

$$A = (I + \frac{\Delta t}{n} A)A \quad \text{and} \quad B = (I + \frac{\Delta t}{n} A)B + \frac{\Delta t}{n} B$$  \hfill (112)$$

during the \(n\) number of time steps, if the time discrete sensitivity matrices are needed.

Notice that the linearized functions (103) are functions of the original variable and not perturbations around the linearization points. If used for NMPC, the iterations within the sequential programming solver uses the perturbations instead of the actual value and a reformulation is required.
