Ion temperature gradient (ITG) modes [1–4] are described by theory as featuring a threshold in the inverse ion temperature gradient length \( R/L_{qi} \equiv R[\nabla T_i]/T_i \), with \( R \) the tokamak major radius) above which the ion heat flux \( (q_i) \) increases strongly with \( R/L_{qi} \). This property leads to a level of stiffness of \( T_i \) profiles, characterizing how strongly they are tied to the threshold. The role of plasma rotation on threshold and stiffness is of high relevance for predicting the performance of future devices, because the core \( T_i \) and fusion power achievable for a given \( T_i \) pedestal depend crucially on threshold and stiffness [5] and future devices are expected to exhibit lower rotation than present devices from which scaling laws are derived.

The role of \( E \times B \) flow shear stabilization [6] has been investigated in nonlinear gyrokinetic and fluid simulations [7–10] and found to result in a threshold upshift. From these studies the well-known “Waltz” quenching rule has been derived: \( \gamma_{E \times B} = \gamma_{\rho \omega E \times B} - \alpha_{E \times B} \) where \( \gamma \) is the instability growth rate, \( \omega_{E \times B} \) is the flow shearing rate and \( \alpha_{E \times B} \sim 1 \) (see [9] for a recent revision). Experimentally, the only study of the impact of rotation on ion threshold and stiffness was performed on JET and reported in [11]. The unexpected result was found that in the plasma core the main effect of rotation is to lower the stiffness rather than increase the threshold, leading to significantly higher \( R/L_{qi} \) in rotating plasmas, well above the levels expected by the threshold upshift foreseen by the Waltz rule.

This Letter presents new experimental results on the combined role of rotation and magnetic shear \( (s) \) in lowering ion stiffness, using transport tools such as \( q_i \) scans and \( T_i \) modulation in plasmas with different safety factor \( (q) \) and rotation profiles. The new empirical hypothesis is proposed that the concomitant presence of high rotational shear and low \( s \) is the condition for achieving ion stiffness mitigation in tokamaks. The relevance of the results for the improved ion core confinement observed in hybrid regimes [12] or ion internal transport barriers (ITBs) [13] is examined based on JET data. A comparison to state-of-art theory is finally presented, discussing quasilinear fluid and gyrofluid and nonlinear gyrokinetic models.

With reference to the main experiment discussed in [11] \( q_i \) scan at \( \rho_{tor} = 0.33 \) by varying the localization of ion cyclotron resonance heating (ICRH) power in \(^{3}\text{He})-D\) minority, reported for the sake of comparison in...
Fig. 1 (color online). \( q_i^{\text{GB}} = q_i / \left( (\rho_i / R)^2 v_{th} n_i T_i \right) \) with \( v_{th} = (T_i / m_i)^{1/2} \). \( \rho_i = (T_i / m_i)^{1/2} / e B \) vs \( R/L_i \). at (a) \( \rho_{\text{tor}} = 0.33 \), (b) \( \rho_{\text{tor}} = 0.64 \) for similar plasmas with different rotations. ●: \( 1 < \omega_{\phi} < 2 \times 10^2 \text{ rad/s}; \) ▲: \( 3 < \omega_{\phi} < 4 \times 10^2 \text{ rad/s}; \) ■: \( 5 < \omega_{\phi} < 6 \times 10^4 \text{ rad/s} \). The dashed black line is indicative of neoclassical transport. The dotted lines represent the critical gradient model (CGM) [11] with different values of \( \chi_i \).

Fig. 1(a), the analysis of the data at \( \rho_{\text{tor}} = 0.64 \) [Fig. 1(b)] indicates that the stiffness reduction due to rotation (observed at \( \rho_{\text{tor}} = 0.33 \)) is not present. This is confirmed also by \( T_i \) modulation data, which yield the slope of the curve as indicated by the two segments. Besides higher values of normalized \( q_i \) in the outer region, a major difference in plasma parameters between the two regions is the magnetic shear \( s = \partial \ln q_i / \partial \ln \rho_i \) with \( s > 1 \) at \( \rho_{\text{tor}} = 0.64 \) while \( s \approx 0.4-0.6 \) at \( \rho_{\text{tor}} = 0.33 \). The rotational shear instead does not show a definite trend with radius. \( s \) is determined by EFT [14] with magnetic, pressure profile, and motional Stark effect (MSE) or polarimeter constraints (statistical error \( \pm 0.05 \)).

ICRH \( q_i \) scans at low and high rotation were carried out in discharges with similar parameters as in Fig. 1’s data set (\( L \) mode, \( B_T = 3.36 \text{ T}, I_p = 1.8 \text{ MA}, n_{e0} = 3-4 \times 10^{19} \text{ m}^{-3} \)), but in which the \( q \) profile, and hence \( s \) and \( s/q \), were varied by lower hybrid preheat, plasma current (\( I_p \)) ramp-up and ramp-down (1.8 to 3 MA in 3.5 s), \( I_p \) overshoot [12]. \( s \) was varied between 0.05 and 0.8 (0.02 < \( s/q \) < 0.5) at \( \rho_{\text{tor}} = 0.33 \) and between 0.75 and 1.45 (0.25 < \( s/q \) < 0.7) at \( \rho_{\text{tor}} = 0.64 \). The aim was to investigate if a low \( s \) value is indeed a concomitant requirement for stiffness reduction due to rotation. Ion threshold and stiffness have been identified as in [11] by placing on- and off-axis 3 MW of ICRH power in \(^3\text{He})-D \) minority at concentrations \( n_{\text{He}}/n_c \sim 6\%-8\% \) and measuring \( R/L_i \) with active charge exchange spectroscopy. \( T_i \) modulation was performed on top. In the high rotation discharges, up to 11 MW of coincident neutral-beam (NBI) power was applied. Figure 2(a) shows the time evolution of the \( q \) profile in a low rotation shot with \( I_p \) ramp-up and off-axis ICRH. \( s \) and \( s/q \) at \( \rho_{\text{tor}} = 0.33 \) and 0.64 are shown vs time in Fig. 2(b). In low NBI discharges, positioning ICRH off-axis implies that the actual \( R/L_i \) at \( \rho_{\text{tor}} = 0.33 \) is a measure of threshold, since \( q_i \sim 0 \). Therefore, the time evolution of \( R/L_i \) directly yields the dependence of threshold on \( s/q \), which is expected from linear theory to be stabilizing. Figure 3 shows \( R/L_i \) vs time at \( \rho_{\text{tor}} = 0.33 \) for the low and high rotation \( I_p \) ramp-up shots, and the linear ITG threshold (similar for both shots) predicted by an analytical formula proposed in [15]

\[
R/L_i^{\text{ITG}} = \frac{4}{3} \left[ 1 + \frac{T_i}{T_e} \right] \left[ 1 + 2 \frac{s}{q} \right] \frac{R}{L_n} < 2 \left[ 1 + \frac{T_i}{T_e} \right] \tag{1}
\]

The increase in measured threshold with time following the increase of \( s/q \) is in good agreement with the expected dependence from Eq. (1). In spite of such threshold increase, it is remarkable that the time behavior of \( R/L_i \) in the high rotation shot is opposite, with \( R/L_i \) lying 3 times above threshold in the early phase and dropping to a factor 1.3 of threshold at late times. At low rotation instead also the on-axis ICRH case (not shown, but virtually identical to the off-axis case) due to high stiffness keeps close to threshold with \( R/L_i \) increasing with time. This observation is a beautiful confirmation of the fact that at high rotation the core \( T_i \) dynamics is completely dominated by stiffness, and the stiffness reduction is more pronounced when the \( q \) profile is flatter (i.e., at early times). At outer radii, where stiffness is high irrespective of rotation, \( R/L_i \) both at low and high rotation keeps close to 7.5. The transport changes in Fig. 3 are accompanied by consistent changes in turbulence measured by correlation reflectometry [16], as discussed in [17].

FIG. 1 (color online). (a) time evolution of MSE \( q_\)\) profile for pulse 77455; (b) \( I_p, s, s/q \) vs time at two radii.

FIG. 2 (color online). (a) time evolution of MSE \( q_\)\) profile for pulse 77455; (b) \( I_p, s, s/q \) vs time at two radii.
Similar observations are made with the other schemes for \( q \) profile variation. The data are summarized in Fig. 4. \( q_i \) values are estimated by the PION ICRH code [18], \( s \) is from MSE. Low rotation data show high stiffness irrespective of \( s \), while at high rotation the stiffness reduction is larger at low \( s \), allowing \( R/L_{T_i} \) up to 10 even at low \( q_i^{\text{GB}} \).

Very high \( R/L_{T_i} (>10) \) is seen at high rotations when the \( q = 2 \) surface is at low \( s \), while at higher \( s \) it does not lead to \( R/L_{T_i} \) increase. This is in line with observations of the beneficial role of low order rational near \( s = 0 \) on turbulent transport [19–22], for which a theoretical basis was proposed in [23]. Such effect of rationals appears as a different phenomenon, which adds to the stiffness mitigation discussed in this Letter. In fact, the effect of rationals is reported both on ions and electrons [19–22] and also in the absence of rotation [19,22], while the stiffness mitigation is only observed on ions and strictly linked to rotation.

The evidence of ion stiffness reduction due to rotation and low \( s \) has profound implications on the interpretation of improved ion core confinement in hybrid plasmas or ion ITBs, proposing an alternative paradigm to the usual one based on \( E \times B \) flow shear threshold up-shift. As a matter of fact, both regimes are experimentally observed in conditions of strong rotation and are lost in the absence of rotation [22,24]. Also, an important role of \( q \) profile manipulation is recognized experimentally (e.g., [12,13]). In [25] the role of both rotation and low \( s \) was already deduced from JET ITB experimental data. Figure 5 (inset) shows typical JET \( q \) profiles in 4 regimes: standard \( H \) mode with fully diffused current, hybrid, optimized shear (OS) and negative shear (NS) ITBs. Both hybrids and ITBs have core regions of very low \( s \). Their position in the \( q_i^{\text{GB}} \) vs \( R/L_{T_i} \) plot at \( \rho_{\text{tor}} = 0.33 \) (Fig. 5) shows that the data populate uniformly the region of high \( R/L_{T_i} \) and low \( q_i^{\text{GB}} \). Some considerations can be made to discriminate if this behavior is mainly due to stiffness or threshold.

In the core of hybrids the linear threshold was found between 3.5 and 5 using GS2 [26], well below the actual \( R/L_{T_i} \). \( \omega_{E \times B} \approx 3–4 \times 10^4 \text{ s}^{-1} \), yielding threshold up-shifts \( \sim 1 \). The profiles then lie well above threshold even at small \( q_i^{\text{GB}} \), indicating low stiffness. This was also confirmed by NBI \( T_i \) modulation (not shown). \( R/L_{T_i} \) vs \( s \) at low and high rotation is plotted in Fig. 6 from a JET \( H \) mode and hybrid database. The scatter is due to the range in parameters in the database, in first place \( R/L_T \) and \( \omega_{E \times B} \) which are from pulse 77477 at different times (cf. Fig. 1). Neoclassical level and GS2 linear threshold for a hybrid are shown. The inset shows \( q \) profiles from MSE for the four scenarios.
While in ITB plasmas the $H$ factor $\sim 1.5$ is all due to large core gradients, in hybrids enhanced pedestal and neoclassical tearing mode (NTM) stabilization also contribute to the $H$ factor. It was shown statistically [30] that the contribution of pedestal to total energy is 20%-40% both in $H$ modes and hybrids and that the $H$ factor up to 1.5 in hybrids is due in equal parts to core and pedestal improvement, with the core part mainly in the ion channel. These findings are consistent with our estimate that an increase in $R/L_{T_i}$ from 6 to 10 due to stiffness mitigation in a region up to $\rho_{tor} = 0.6$ at fixed pedestal leads to $\Delta H \sim 0.2$. With regard to NTMs, experiments show [31] that strong NTM onset leads to an abrupt drop of the $H$ factor to $\sim 1$, with a deterioration of $T_i$ profile mainly caused by the braking of plasma rotation. This does not contradict the fact that, when NTMs are weak or absent, the core transport dynamics discussed above are at play.

Finally, we address the state of the art of theory predictions on the effect of rotation on ion transport. In widely used quasi-linear transport models, such as WEILAND [32] or GLF23 [33], which apply the Waltz rule on a given and restricted choice of spectral wave numbers, rotation introduces only a small threshold up-shift and not a change in slope. The results by the WEILAND model for a shot with $s = 0.57$ are shown in Fig. 8(a) without and with rotation [$\gamma_E = \omega_{E \times B} / c_s / a \sim 0.1$, with $c_s = (T_e / m_i)^{1/2}$]. On the other hand, the more recent gyrofluid TGLF model [34], which makes use of full spectra, indicates a change in slope [Fig. 8(b)], in particular, in the region of the knee, at the transition between fully developed turbulence and zonal flows. The simulations scan $R/L_{T_i}$ and $R/L_{T_e}$ in a prescribed ratio (from experiment) without and with rotation. This effect may be due to differential suppression of turbulence at various wavelengths, with more suppression of the low stiffer ones. The change in stiffness with rotation is larger at low $s$ [Fig. 8(d)] as in experiments. The WEILAND model has been modified to include the dependence.
of the fastest growing mode number on rotation [35], obtaining results very similar to TGLF [Figs. 8(a) and 8(e)].

To verify these results, nonlinear flux-tube electrostatic gyrokinetic simulations using GYRO [36] have been made [Fig. 8(c)], with background rotation and electron-ion collisions, for the same parameters as with TGLF. The box size is $62 \times 222$ $\rho_s$ ($\rho_s = (T_e m_i)^{1/2}/eB$) with 64 toroidal modes from $k_r \rho_s = 0.028$ to $k_r \rho_s = 1.78$ and with a minimum $k_r \rho_s = 0.1$ and max $k_r \rho_s = 6.47$ corresponding to a radial resolution $6 \times \rho_B = 0.24$. The radial box size is $\Delta r/a = 0.125$. At low $R/L_T$, very large $n = 0$ (zonal) electrostatic potential fluctuations are found, which strongly reduce the transport and obligate us to perform simulations exceeding $1000a/c_s$. The same results are obtained with double radial box size keeping the same radial resolution. We note that runs with a reduced number of toroidal modes do not deliver the same strength of zonal flows. With 64 modes, due to the large zonal flows, turbulent transport is rapidly quenched to zero near threshold and there is no hint of stiffness mitigation at high rotation, but basically only a threshold up-shift. Similar results were obtained with GKW [37] as reported in [17] and recently with GS2 on a different case [38], Fig. 3(a)]. Global simulations did not yield significant changes at this inner radius. Since the mechanisms mentioned above as a possible origin of the stiffness reduction in quasi-linear models are also included, and with most resolved treatment, in nonlinear gyrokinetic models, we have to admit that presently the impact of rotation on ion stiffness remains an open issue on the theory side. It deserves further work because, although numerically challenging, the marginality region is the operating domain of fusion devices. We also note that none of the models in Fig. 8 in fact reproduce correctly the low $R/L_T$, of the low rotation data, either due to not high enough stiffness or to the presence of a nonlinear (Dimits) threshold up-shift. This is also an open issue.

In summary, JET experiments show that ion stiffness is reduced by low $s$ and high rotation. This indicates that advanced tokamak scenarios in future devices will require sufficient rotational shear and the capability of $q$ profile manipulation.

Nonlinear gyrokinetic simulations were performed on the parallel server Power 6 (Vip) of the IPP-MPG Rechenzentrum Garching, Germany. This work was supported by EURATOM and carried out within the framework of EFDA. The views and opinions expressed herein do not necessarily reflect those of the European Commission. This work was done under the JET-EFDA work programme [39].
