Preprint online version: January 12, 2011

ABSTRACT

The performance of the Planck instruments in space is enabled by their low operating temperatures, 20 K for LFI and 0.1 K for HFI, achieved through a combination of passive radiative cooling and three active mechanical coolers. Active coolers were chosen to minimize straylight on the detectors and to maximize lifetime. The scientific requirement for very broad frequency led to two detector technologies with widely different temperature and cooling needs. This made use of a helium cryostat, as used by previous cryogenic space missions (IRAS, COBE, ISOPHOT, AKARI), infeasible. Radiative cooling is provided by three V-groove radiators and a large telescope baffle. The active coolers are a hydrogen sorption cooler (< 20 K), a He Joule-Thomson cooler (4.7 K), and a He<sup>3</sup>-He dilution cooler (1.4 K and 0.1 K). The flight system was at ambient temperature at launch and cooled in space to operating conditions. The bolometer plate of the High Frequency Instrument reached 93 mK on 3 July 2009, 50 days after launch. The solar panel always faced the Sun, shading the rest of Planck, and operates at a mean temperature of 384 K. At the other end of the spacecraft, the telescope baffle operates at 42.3 K and the telescope primary mirror operates at 35.9 K. The temperatures of key parts of the instruments are stabilized by both active and passive methods. Temperature fluctuations are driven by changes in the distance from the Sun, sorption cooler cycling and fluctuations in gas-liquid flow, and fluctuations in cosmic ray flux on the dilution and bolometer plates. These fluctuations do not compromise the science data.

Key words. Cosmology – Cosmic microwave background – Space instrumentation – Instrument design and calibration

1. Introduction

Planck is the third generation space mission to measure the anisotropy of the cosmic microwave background (CMB). It observes the sky in nine frequency bands covering 30–857 GHz with high sensitivity and angular resolution from 3′ to 5′. The Low Frequency Instrument (LFI; Mandolesi et al. 2010; Bersanelli et al. 2010; Mennella et al. 2011) covers the 30, 44, and 70 GHz bands with amplifiers cooled to 20 K. The High Frequency Instrument (HFI; Lamarre et al. 2010; Planck HFI Core Team 2011a) covers the 100, 143, 217, 353, 545, and 857 GHz bands with bolometer-telescope reflectors provided by a collaboration between ESA and a scientific consortium led and funded by Denmark.

* Corresponding author: C. R. Lawrence <charles.lawrence@jpl.nasa.gov>
The unprecedented performance of the *Planck* instruments in space is enabled by their low operating temperatures, 20 K for LFI and 0.1 K for HFI, achieved through a combination of passive radiative cooling and three active coolers. This architecture is unlike that of the previous CMB space missions, the *Cosmic Background Explorer (COBE)* (Boggess et al. 1992) and the *Wilkinson Microwave Anisotropy Probe (WMAP)* (Bennett et al. 2003). *WMAP* relied on passive radiative cooling alone which, while simpler, resulted in a higher operating temperature for its amplifiers and a higher noise temperature. Additionally, purely passive cooling is unable to reach the sub-Kelvin operating temperatures required by HFI’s high-sensitivity bolometers. By contrast, *COBE* used a liquid helium cryostat to enable cooling of the bolometers on its Far-Infrared Absolute spectrophotometer (FIRAS) instrument (Mather et al. 1990) to 1.5 K. This approach was not adopted for *Planck* as it would restrict the on-orbit lifetime of the HFI, require additional coolers to reach sub-Kelvin temperatures, and be entirely infeasible for cooling the active heat load from the LFI.

The thermal architecture for a CMB mission is critical to its success, as is its implementation and performance. In this paper we describe the design and in-flight performance of the mission-enabling *Planck* thermal system.

2. Thermal Design

2.1. Overview and philosophy

The overall thermal design of *Planck* can be understood from Fig. 1. The solar panel always faces the Sun and the Earth, the only two significant sources of heat in the sky, and operates at 385 K. The service vehicle module (SVM), containing all the usual electronic components of a spacecraft, operates at room temperature. The telescope at the opposite end of the flight system operates below 40 K. The detectors at the focus of the telescope are actively cooled to 20 K (amplifiers) or 0.1 K (bolometers). Between the SVM and the “cold end,” aggressive measures are taken to minimize heat conduction and to maximize the radiation of heat to cold space. These measures include low-conductivity support elements, three V-groove radiators, and a telescope baffle with low emissivity inside and high emissivity outside.

2.1.1. Mission design, scientific requirements, and thermal architecture

*Planck* is designed to extract all information in the temperature anisotropies of the CMB down to angular scales of 5°, and to provide a major advance in the measurement of polarization anisotropies. This requires both extremely low noise and broad frequency coverage from a few tens to several hundred gigahertz to separate foreground sources of radiation from the CMB. The necessary noise level can be reached only with cryogenically-cooled detectors. The lowest noise is achieved with amplifiers cooled to ≤ 20 K and bolometers cooled to ≤ 0.1 K. Temperature fluctuations must not compromise the sensitivity. Additional requirements on *Planck* that affect the thermal design include: 1) no deployables (e.g., a shield that could block the Sun over a large solid angle); 2) no optical elements such as windows between the feed horns and telescope; 3) no cryostat or stored cryogens; 4) an off-axis telescope below 60 K; 5) feed horns for the bolometers below 5 K, and a bolometer environment below 2 K; and 6) reference targets (loads) for the pseudo-correlation amplifier radiometers below 5 K to minimize 1/f noise. These requirements led to a design that includes the following.

- The general architecture shown in Fig. 1, with the solar panel acting as a Sun shield, and temperature decreasing along the spin axis toward the cold end with a passively cooled telescope.
- Detectors based on amplifiers at 30, 44, and 70 GHz, and on bolometers at 100, 143, 217, 353, 545, and 857 GHz.
- Three active coolers.
  1. The “sorption cooler” (Fig. 2), a closed-cycle sorption cooler using hydrogen as the working fluid with a Joule-Thomson (JT) expansion, which produces temperatures below 20 K. The sorption cooler cools the LFI focal plane to < 20 K and provides precooling to lower temperature stages.
  2. The “He-JT cooler” (Fig. 3), a closed-cycle cooler using a Stirling cycle compressor and 4He as the working fluid with a JT expansion, which produces temperatures below 5 K. The 4He-JT cooler cools the HFI focal plane and the LFI reference loads to < 5 K and provides precooling to the dilution cooler.
  3. The “dilution cooler” (Fig. 4), a 3He–4He dilution cooler that vents combined 3He and 4He to space, and which produces temperatures of 1.4 K through JT expansion of the 4He and 3He, and ~ 0.1 K for the bolometers.

- A “warm launch” scenario, in which the entire flight system is at ambient temperature for launch, and the detectors are cooled in space by a combination of passive and active cooling.

2.1.2. Requirements on the coolers

The coolers were required to deliver temperatures of < 20 K, < 5 K, and 0.1 K, continuously. Although use of proven technology is preferred in space missions, the special requirements of *Planck* led to the choice of two new-technology coolers. The first is a hydrogen sorption cooler developed by the Jet Propulsion Laboratory in California, which provides a large heat lift with no mechanical compressors (avoiding vibration). The sorption cooler requires precooling of the hydrogen to ≤ 60 K. The precooling temperature required by the 4He-JT cooler, which is supplied by the sorption cooler, is ≤ 20 K. This interface temperature is critical in the cooling chain: the 4He-JT cooler heat load increases with the interface temperature when, at the same time, its heat lift decreases. Thus the goal for the precool temperature supplied by the sorption cooler was 18 K, with a strict requirement of ≤ 19.5 K to leave enough margin to the cooling chain.

The second new-technology cooler is a 3He–4He dilution cooler. In the laboratory, temperatures of 100 mK can be achieved with both adiabatic demagnetization refrigerators (ADR) and dilution refrigerators. Space qualified ADRs were developed in the 1980s, but none had been used successfully
in space at the time Planck was designed. Furthermore, ADRs require high magnetic fields and cycling, not easily compatible with continuous measurements and the very high stability requirements of Planck.

The microgravity dilution cooler principle was invented and tested by A. Benoît (Benoît et al. 1997) and his team at Institut Néel, Grenoble, and developed into a space qualified system by DTA Air Liquide (Triqueneaux et al. 2006) under a CNES technology contract led by the system group at IAS under the direction of Guy Guyot. It provides two stages of cooling at 1.4 K and 100 mK. The total heat lift requirement at 100 mK was 0.6 µW, and could be achieved with an open circuit system carrying enough $^3$He and $^4$He for the mission. The precollision temperature required was less than 4.5 K, which could be provided by the $^4$He JT expansion cooler mentioned above using space qualified mechanical compressors developed by RAL and ASTRIUM-UK (formerly British Aerospace) under ESA technology development contracts. The net heat lift needed from this cooler is 15 mW at the highest precollision temperature (20 K). Since bolometers are sensitive to microvibrations, this cooler includes a new technology vibration control system developed under an ESA technology contract for the Herschel Space Observatory (formerly FIRST) although not used on it.

2.1.3. Redundancy philosophy

A redundant sorption cooler system was required because both instruments depend on it. Furthermore the hydride used in the sorption beds ages. The other two coolers coolers are only needed by the HFI, and were not required to be fully redundant. The critical elements of the dilution cooler are passive. Although the flow of $^3$He and $^4$He is adjustable, a minimum flow is always available. The only single point failure is the opening of the valves on the high pressure tanks of $^3$He and $^4$He at the start of the mission. Making those redundant would increase the risk of leaks and does without improving reliability significantly. The compressors used in the $^4$He-JT cooler have good flight heritage. The vibration control system was not considered a single point failure for the high frequency instrument, although its failure would degrade performance significantly. The $^4$He-JT cooler provides the reference loads for the LFI, and is thus a quasi-single point failure; however, it was not made redundant because of its good flight heritage and in view of the extra resources it would have required from the spacecraft.

2.1.4. The critical importance of passive cooling

Nearly 14 kW of solar power illuminates the solar panel. Of this, less than 1 W reaches the focal plane, a result of careful thermal isolation of components, extremely effective passive (radiative) cooling from the V-grooves and the telescope baffle, and the overall geometry. The low temperatures achieved passively have
Fig. 2. Sorption cooler system. The system is fully redundant. The orange box houses one of the compressor assemblies, mounted on one of the warm radiator panels, which faces cold space. Heat pipes run horizontally connecting the radiators on three sides of the service vehicle octagon. The second compressor assembly is the black box on the right. A tube-in-tube heat exchanger carries the high and low pressure hydrogen gas from the compressor assembly to the focal plane assembly, with heat-exchanging attachments to each of the three V-grooves. The colors indicate temperature, from warm (red, orange) to cold (blue).

Fig. 3. $^4$He-JT cooler system. The back-to-back compressors are highlighted in gold on the left-hand side of the service vehicle, adjacent to control electronics boxes. The high and low pressure $^4$He gas tubes connecting the compressors with the JT valve in the focal plane are colored from purple to blue, indicating temperature as in Fig. 2.
Planck Collaboration: The thermal performance of Planck

Fig. 4. Dilution cooler system. Four high pressure tanks of $^3$He and $^4$He are highlighted in silver. The dilution cooler control unit (DCCU), to which piping from the tanks and to the focal plane unit is attached, is highlighted on the left.

a dramatic effect on the design of the active coolers. In particular, the efficiency and heat lift of the sorption cooler increase rapidly as the temperature of the precooling provided by the V-grooves, especially V-groove 3, decreases. The $^4$He-JT cooler heat lift also increases as its precool temperature—the ∼18 K provided by the sorption cooler—decreases. The low temperatures of the primary and secondary mirrors mean that their thermal emission contributes negligibly to the overall noise of the instruments; and the radiative heat load from the baffles and mirrors on the focal plane unit (FPU) is extremely low. None of this could work as it does without the passive cooling.

2.2. Passive components

2.2.1. V-grooves

The “V-groove radiators” are three cones built from flat wedges of carbon fibre honeycomb panel covered with aluminium face sheets. All surfaces are low emissivity except the exposed top of V-groove 3, which is painted black for good radiative coupling to cold space. The cone vertex angles are about 7° smaller for the successive V-grooves. Facing cones are not parallel, therefore, and photons between them are redirected to cold space in a few reflections. V-grooves are thus extremely effective at both thermal isolation and radiative cooling, with many advantages over multilayer insulation (MLI), including negligible outgassing after launch.

2.2.2. Telescope baffle

The telescope baffle provides both radiative shielding and passive cooling. Its interior is covered with polished aluminium for very low emissivity, while its outside is covered with open hex-cells painted black, for maximum emissivity.

2.3. Active components

2.3.1. Sorption cooler and warm radiator

Planck has a fully redundant hydrogen sorption cooler system (Bhandari et al. 2004). Each cooler includes a compressor assembly, warm radiator, piping assembly (including heat exchangers on three V-groove radiators), a JT expander, and control electronics. The major components of the system are shown in Fig. 2. There are no moving parts except for passive check valves. The heart of the compressor is six “compressor elements” containing a La$_{1.0}$Ni$_{1.78}$Sn$_{0.22}$ alloy that absorbs hydrogen at ∼1/3 atmosphere at ∼270 K and desorbs it at ∼30 atmospheres at ∼460 K. By varying the temperature of the six beds sequentially with resistance heaters and thermal connections to the warm radiator, a continuous flow of high-pressure hydrogen is produced.

Sorption coolers provide vibration-free cooling with no moving parts, along with great flexibility in integration of the cooler to the cold payload (instrument, detectors, and telescope mirrors) and the warm spacecraft. No heat is rejected in or near the focal plane. The refrigerant fluid in the sorption coolers is hydrogen, selected for operation at a temperature of ∼17 K. The two Planck sorption coolers are the first continuous cycle sorption coolers to be used in space.

Table 1 gives the sorption cooler system requirements. The temperature stability requirement is an inadequate simplification of a complicated reality. Fluctuations in the temperatures of the sorption cooler interfaces to the LFI and HFI have no intrinsic significance. What matters is the effect of temperature fluctuations on the science results. Fluctuations at the cooler interfaces with HFI and LFI (LVHX1 and LVHX2, respectively) propagate to the detectors themselves through complicated conductive and radiative paths (quite different for the two instruments). Temperature controls, passive components of varying emissiv-
in the optical paths, the structure of the detectors and the effect of thermal fluctuations on their output, and the effects of the spinning scan strategy and data processing all must be taken into account. Fluctuations at frequencies well below the spin frequency (16.67 mHz) cannot be from the sky, and are easily removed by the spin and data processing. Fluctuations at frequencies well above the spin frequency are heavily damped by the front-end structure of the instruments. None of the factors listed was known or could be calculated with any fidelity at the time a cooler fluctuation requirement had to be devised. It was not possible, therefore, to derive a power spectral density limit curve—the only kind of specification that could capture the true requirements—with any fidelity. We will return to this point in § 7.

The compressor assembly (SCC) comprises six identical compressor elements, each filled with $\text{La}_2\text{Ni}_4\text{Sn}_0.22$ metal hydride and capable of being independently heated or cooled. Each compressor element is connected to both the high pressure and low pressure sides of the piping system through check valves that allow gas flow in a single direction only. The high pressure is stabilized by a 4 litre ballast tank, the high-pressure stabilization tank (HPST). On the low pressure side, the low pressure storage bed (LPSB), filled with hydride and maintained at a temperature near that of the warm radiator, stores a large fraction of the $\text{H}_2$ required to operate the cooler during flight and ground testing while minimizing the pressure in the non-operational cooler during launch and transportation.

The compressor elements are taken sequentially through four steps: heat up to pressurize; desorb; cool down to depressurize; absorb. At a given instant, one of the six compressor elements is heating up, one is desorbing, one is cooling down, and three are absorbing. Heating is achieved by electrical resistance heaters. Cooling is achieved by thermally connecting the compressor element to the so-called “warm radiator”; whose temperature is controlled (§ 2.4.3) by electrical heaters at a temperature in the range $272 \pm 10 \text{ K}$. A single compressor element comprises a cylinder supported at its ends by low thermal conductivity tubes connected to a larger semi-cylinder with a flat side. The inner cylinder contains the $\text{La}_2\text{Ni}_4\text{Sn}_0.22$; the outer semi-cylinder creates a volume around the inner cylinder, and its flat side is bolted to the “warm radiator.” The volume between the two is evacuated or filled with low pressure hydrogen by a gas-gap heat switch using a second metal hydride, ZrNi. When filled with low pressure hydrogen, there is a good thermal connection from the inner hydride bed to the warm radiator. When hydrogen is evacuated, the inner hydride bed is thermally isolated, and can be heated up efficiently.

The warm radiator covers three of the eight panels of the SVM. The two compressor assemblies are mounted on the end panels of the three, each of which contains 16 straight heat pipes running parallel to the spacecraft spin axis and perpendicular to the compressor elements. These heat pipes maintain a nearly isothermal condition across the panel, in particular distributing the heat of the compressor element that is in the cooldown cycle. Eight long, bent, heat pipes run perpendicular to the others, connecting all three panels of the radiator together. The external surfaces of all three panels are painted black.

Upon expansion through the JT valve, hydrogen forms liquid droplets whose evaporation provides the cooling power. The liquid/vapour mixture then flows through two liquid/vapour heat exchangers (LVHX) thermally and mechanically coupled respectively to the HFI interface, where it serves to precool for the $^3\text{He}$-JT cooler (§2.3.2) and the $^3\text{He}$-$^4\text{He}$ dilution cooler (§2.3.3), and to the LFI interface, where it cools the LFI focal plane assembly to $\sim 20 \text{ K}$. Any remaining liquid/vapour mixture flows through a third LVHX, which is maintained above the hydrogen saturated vapour temperature. This third LVHX serves to evaporate any excess liquid that reaches it, preventing flash boiling and thereby maintaining a nearly constant pressure in the low-pressure plenum. Low-pressure gaseous hydrogen is recirculated back to the cool sorbent beds for compression.

Regulation of the system is done by simple heating and cooling: no active control of valves is necessary. The heaters for the compressors are controlled by a simple timed on-off heater system.

The flight sorption cooler electronics and software were developed by the Laboratoire de Physique Subatomique et de Cosmologie (LPSC) in Grenoble. These electronics and their controlling software provide for the basic sequential operation of the compressor beds, temperature stabilization of the cold end, and monitoring of many of the cooler performance parameters. In addition, they automatically detect several kinds of failure modes and adapt operations accordingly. Finally, they are sufficiently flexible to allow the operational parameters to be adjusted in flight to maximize the lifetime and performance of the sorption coolers.

The total input power to the sorption cooler at end of life (maximum average power) is 470 W. Another 110 W is available to operate the sorption cooler electronics.

capacity between the JT orifice and the rest of the HFI. It is attached to the bottom of the 4 K box of the HFI FPU as can be seen in Fig. 5. It provides cooling for the 4 K shield and also precooling for the gas in the dilution cooler pipes described in the next section.

The cooling power and thermal properties of the $^4$He-JT cooler, measured by the RAL team at subsystem level and then in the system thermal vacuum tests, are summarised in the following relationships, which depend linearly on the adjustable parameters in the vicinity of the flight operating point:

$$HL_{\text{max}} = 15.9 \text{ mW} + 6.8(\Delta S - 3.45 \text{ mm})$$  
$$-1.1(T_{\text{pc}} - 17.3 \text{ K}) + 0.6(P_{\text{fill}} - 4.5 \text{ bar});$$  

(1)  

Heatload = 10.6 mW + 0.5($T_{\text{pc}}$ - 17.3 K)  
+0.065($T_{\text{vg}3}$ - 45 K) + Heaters;  

(2)  

$$T_{\text{JT4K}} = 4.4 \text{ K} - 0.24(\Delta S - 3.45 \text{ mm});$$  

(3)  

where $T_{\text{pc}}$ is the pre-cooling temperature, $T_{\text{vg}3}$ is the temperature of V-groove 3, $\Delta S$ is the stroke half amplitude of the compressors, and $P_{\text{fill}}$ is the helium filling pressure.

The heat load on the 4 K box was predicted by the thermal model and verified on the flight model during the CSL thermal balance/thermal vacuum test. Performance in flight was unchanged (§4.1.2).

The stroke amplitude, and to some degree the sorption cooler precooler temperature, are adjustable in flight. The interface with the sorption cooler, including the warm radiator temperature, is the most critical interface of the HFI cryogenic chain. The $^4$He-JT cooler heat load increases and its heat lift decreases as the sorption cooler precooler temperature increases (see Fig. 6). The $^4$He-JT cooling power margin depends strongly on this temperature, itself driven mostly by the temperature of the warm radiator. Warm radiator temperatures of $272 \text{ K}$ ($\pm 10 \text{ K}$, §2.3.1) lead to sorption cooler temperatures between $16.5 \text{ K}$ and $17.5 \text{ K}$ (Bersanelli et al. 2010). It can be seen from Fig. 6) that at $20 \text{ K}$ precooler temperature even using the largest possible stroke amplitude leaves no margin.

The two mechanical compressors produce microvibrations and also induce electromagnetic interference potentially affecting the science signals of bolometers. The risks associated with these effects were taken into account early in the design of the HFI by phase-locking the sample frequency of the data to a harmonic of the compressor frequency.

**Fig. 6.** Heat lift of the $^4$He-JT cooler as a function of precool temperature, stroke amplitude $\Delta S$, and proportional, integral, differential (PID) control power. For $\Delta S = 3.45 \text{ mm}$, a precooler temperature of $19.5 \text{ K}$ gives the minimum required heat lift (Table 2) of $13.3 \text{ mW}$. The in-flight precooler temperature of $\sim 17.0 \text{ K}$ (vertical dotted line, and Table 10) allows the use of a low stroke amplitude, minimising stresses on the cooler, and provides a large margin in heat lift.
components at their proper temperature, minimizes the heat flux to the SVM thermal control system maintains all SVM components at their proper temperature, minimizing the heat flux to the SVM payload module, and guarantees a stable thermal environment to the payload module.

The dilution cooler operates on an open circuit using a large quantity of $^4$He and $^3$He stored in four high pressure tanks. The major components of the system are shown in Fig. 4, including a JT expansion valve producing cooling power for the “1.4 K stage” of the FPU and pre-cooling for the dilution cooler. The gas from the tanks (300 bar at the start of the mission) is reduced to 19 bar through two pressure regulators, and the flow through the dilution circuits is regulated by a set of discrete restrictions chosen by telecommand. The flow rates for different configurations of the restrictions are given in Table 3 for the hot spacecraft case. The flows depend on the restriction temperature through changes of the helium viscosity.

The heat lift margin $HL_{\text{margin}}$ (available for temperature regulation) is determined by:

- $He_{\text{flow}}$, the flow rate of the helium isotopes in μmol s$^{-1}$ given by the chosen restriction configuration; for each restriction the flow is expressed when the temperature of the dilution cooler control unit (DCCU) is at 273 K.
- $T_{\text{DCCU}}$, the temperature of the DCCU in flight
- the heat loads from the bolometer plate, determined by the temperature difference between $T_{\text{bolo}}$ and $T_{\text{dilu}}$, and from the 1.4 K stage at a temperature of $T_{1.4K}$.
- $T_{\text{dilu}}$, the temperature of the dilution cold end

This margin is given by:

$$HL_{\text{margin}} \text{[nW]} = 3.2 \times 10^{-3} \times He_{\text{flow}} [\mu \text{mol s}^{-1}] \times \left( \frac{T_{\text{DCCU}}}{273} - 1 \right)^{1.5} - 250 \left( T_{1.4K} - 1.28 \right) - 20 \left( T_{\text{bolo}} - T_{\text{dilu}} \right) - 490$$  \hspace{1cm} (4)

where the last three lines are, respectively, the heat loads from the 1.4 K stage, the bolometer plate, and fixed conduction parasitics, all in nanowatts.

As shown in Fig. 7, even at the highest temperature of the dilution panel in the spacecraft (19°C, thus minimum flow for a given restriction due to higher viscosity of the helium), 101 mK can be achieved in flight with the lowest flow ($F_{\text{min}2}$), with 115 nW of power available for regulation, and with the extra heat input in flight from cosmic rays and vibration.

### 2.3.3. Dilution cooler

The downlink transponder dissipates 70 W when on. A heater on the panel is not close enough to compensate effectively for the varying dissipation of the transponder. During initial checkout of the flight system, downlink was continuous and the transponder did not produce temperature fluctuations in the SVM. On 6 July 2009, 53 days after launch, however, downlinks were reduced to 6 h/day. On 8 August 2009, 100 days after launch, they were reduced further to the normal operating time of 3 h/day. During those hours, the power dissipated by the transponder caused a rise in the temperature of the $^3$He and $^4$He tanks, increasing their pressure, and affecting the flow of gas in the dilution cooler. The temperature of the LFI radiometer back-ends, mounted on the SVM, also varied. Both of these led to fluctuations in the detector outputs that were easy to see. Because the timescale was long, the spin of the spacecraft and normal processing removed the effects in the data essentially completely. Nevertheless, it was decided to leave the transponder on all the time. This was done on 25 January 2010 (operational day number OD 258), leading to a reduction of the daily fluctuations of the relevant temperatures in the SVM by up to an order of magnitude (see §5.1 and Fig. 26).
Another three panels are dedicated to the sorption coolers (§2.3.1). The sorption cooler compressor elements have intermit-tent high dissipation. To minimize the impact on the rest of SVM, the sorption cooler cavity is internally wrapped by MLI. To maintain the sorption coolers above their minimum temperature limits (253 K non-operating and 260 K operating), several heaters have been installed on the eight horizontal heat pipes and grouped in seven heater lines working at different temperatures. Temperature control of the warm radiator is described in §2.4.3 below.

The warm compressors of the 4He-JT cooler are installed on another panel equipped with heaters to maintain a minimum temperature.

The LFI radiometer electronic backend units (REBAs) and the dilution cooler control unit (DCCU) are installed on the last panel. Heaters with PID control maintain the REBAs and the DCCU at a stable temperature at 2.75 °C. The top surface of the SVM is covered with 20 layers of MLI to minimize radiation onto the payload.

2.4.2. Thrusters, STR switchover, SCS tuning

No attempt is made to control the temperature of the thrusters or their heating effect. Fig. 8 shows the temperature of the 20 N thrusters at the time of orbit correction manoeuvre number 5 on 26 February 2010. Fig. 8 shows the effect of the thruster firings on the temperature of one of the 4He tanks. The manoeuvre delta-V began at UT 23:01:50 and ended at 23:09:14, with a commanded size of 4.269666 cm s−1. The corresponding pressure increase in the helium tank leads to an increased flow rate for a while, but the downstream controls on temperature adjust so there is no detectable thermal effect on the detectors.

During the first 18 months of the mission, three unexpected star tracker switchovers occurred, two of them during science operations. The longest lasted 10 hr. It is expected that swapping electrical power from one star tracker to the other changes the relative alignment of the star tracker platform with the focal plane due to thermal effects. Alignment stability during switchover will be measured precisely by reobserving the same sky immediately after a scheduled switchover; then the effect can be removed from the data if the redundant star tracker has to be used.

2.4.3. Warm radiator

The warm radiator plays a critical role in the operation of the sorption cooler. It is the means by which the heat generated inside the compressor elements during heat-up and desorption is rejected to cold space. (Most of the heat lifted from the focal plane is rejected to space by the V-groove radiators.) The temperature of the warm radiator determines the temperature of the hydride beds during the absorption part of the cooler cycle. The lower the temperature, the lower the pressure of hydrogen on the low pressure side of the JT expansion, and therefore the lower the temperature of the thermal interfaces with the HFI and LFI (LVHX1 and LVHX2, respectively). The strict requirement on the temperature of LVHX1 given in Table 1 translates into a requirement on the temperature of the warm radiator.

Temperature control of the warm radiator is achieved with seven independent heater lines. The temperature of the warm radiator depends on the total heat input from the sorption cooler plus the heaters. A listing of the heaters along with their control bands is given in Table 4. The average of three warm radiator thermistors, calculated once per minute for each loop, is used for control of all seven heaters.

2.4.4. 20K stage

LVHX1 provides a temperature below 18 K, with fluctuations driven by the cooler (bed-to-bed variations, cycling, instabilities in the hydrogen liquid-gas flow after the JT, etc.). Stabilization of the temperature of this interface with the HFI is not necessary, as temperature control of the subsequent colder stages is more efficient and very effective.

LVHX2 provides a temperature of about 18 K. To reduce cold end fluctuations transmitted to the radiometers, an intermediate stage, the temperature stabilization assembly (TSA, Fig. 9), is inserted between LVHX2 and the LFI FPU. The TSA comprises a temperature sensor and heater controlled by a hybrid PID and predictive controller, plus a high-heat-capacity thermal resistance. The set-point temperature of the TSA is an adjustable parameter of the sorption cooler system, chosen to provide dynamic range for control, but not to require more than 150 mW of power from the heater. As the hydride in the sorption cooler ages, the return gas pressure and thus the temperature of LVHX2 rise slowly. The temperature of the warm radiator (§2.4.3) also affects the temperature of LVHX2. Small adjustments of the set-point temperature are required now and then. There is no other temperature regulation in the LFI focal plane.

The heater/thermometer is redundant. The thermal resistance between LVHX2 and the TSA is a large parameter (§2.4.3) which affects the temperature of LVHX2. Small adjustments of the set-point temperature are required now and then. There is no other temperature regulation in the LFI focal plane.

2.4.5. 4K, 1.4K, and 0.1 K stages

The noise produced by thermal fluctuations of sources of stray radiation should be small relative to the photon noise if no correction is applied to the signal. This leads to a conservative requirement (Lamarre et al. 2003) that the temperatures of the

</table>
cryogenic stages that support optical elements must meet the stability requirements given in Table 5.

Active thermal control of the 4 K, 1.4 K, and 100 mK stages (Piat et al. 2003, 2000) is needed to meet these requirements. Temperature is measured with very sensitive thermometers made of optimised NTD Ge (Piat et al. 2001, 2002) and read out by the same electronics as for the bolometers. Details on the temperature stability tests and results are given by Pajot et al. (2010).

Regulation of the stages is achieved by active control of low frequency fluctuations ($f \leq 0.1$ Hz) and passive filtering of high frequency fluctuations ($f \geq 0.1$ Hz). The active system uses the sensitive NTD Ge thermometers mentioned above. The regulation algorithm is a PID control implemented in the on-board software. Each heater is biased by a 24 bit ADC (made of two 12 bit ADCs). A passive electrical circuit connects the ADC to the heater to fix the maximum heat deposition and the frequency range.

4 K—The main sources of thermal fluctuations on the 4 K plate are the $^4$He-JT cooler and the mechanical supports to LFI (Fig. 10), which conduct thermal fluctuations introduced by the sorption cooler on the LFI chassis. The actively controlled heater is a ring located at the top of the cylindrical part of the 4 K box.

Table 5. Temperature stability requirements on HFI components, over the frequency range 16 mHz–100 Hz.
heater ribbon

1.4K resistive

Fig. 10. Thermal control architecture of the 4 K and 1.4 K stages (left) and the 0.1 K stage (right).

(Fig. 10). The passive filtering results from the thermal path and the heat capacity of the 4 K plate and box.

1.4 K—The 1.4 K stage is a cylindrical box with a conical top (Fig. 10). Temperature fluctuations arise at two places: (i) at the bottom of the box where the JT expansion is located; and (ii) on the side of the cylinder, at about 2/3 of its length, where mechanical supports attach at three points symmetrically located on the circumference. To use the natural symmetry of this stage, the heater is a ribbon placed after the mechanical supports. A sensitive thermometer on the 1.4 K filter plate is used as the sensor in the regulation loop. Passive filtering is provided by the long thermal path between the sources of fluctuations and the filters, as well as by the heat capacity of the optical filters plate.

0.1 K—The main sources of temperature fluctuations on the 100 mK bolometer plate are the dilution cooler itself, the background radiation, and fluctuations in cosmic rays. This stage has been carefully optimised, since it is one of the main sources of noise on the bolometers. The main principles of the 100 mK architecture are (Piat 2000): (i) Control all thermal paths between sources of temperature fluctuations and parts that must be stable; (ii) Actively control the structure around the bolometer plate and the bolometer plate itself to ensure long period stability, (iii) Low-pass filter the structure to remove artefacts of the active system and to allow short-term stability.

Figure 10 shows a schematic of the 100 mK architecture. The mechanical support of the heat exchanger consists of struts of niobium-titanium alloy and plates used to thermalise the heat exchanger tubes and the wiring. A counterflow heat exchanger is thermally connected to all plates except the coldest one (the dilution plate). It goes directly from the next-to-last plate (at about 105 mK) to the dilution exchanger. The dilution exchanger is a cylinder around which the dilution tubes are wound. The first regulation system (PID1) is directly attached to this cylinder and provides stability on long time scales. It is a hollow Nb-Ti alloy cylinder containing an “I” shaped piece of copper with redundant PIDs (i.e., two heaters and two thermometers) in the thin part of the I (Piat et al. 2003). Its function is to actively damp fluctuations induced by the dilution cooler. The dilution plate supports the PID1 box, the wiring, and the connectors needed for PID1. Yttrium-holmium (YHo) struts support the bolometer plate. They provide passive filtering with a thermal time constant of several hours thanks to a very large increase of heat capacity in YHo at low temperature (Madet 2002; Piat 2000). The bolometer plate is made of stainless steel covered with a thin (250 μm) film of copper, itself covered with a thin gold plating. This architecture has been defined after thermal simulation of high energy particle interactions. A second regulation stage (PID2) is placed directly on the bolometer plate. It ensures control of the absolute temperature of the bolometer plates and compensates for fluctuations induced by external sources such as cosmic rays or background radiation fluctuations. Ground tests showed that the regulation systems would meet requirements as long as the in-flight fluctuations of the heat loads did not exceed predictions.

2.5. Dependencies

The Planck cooling chain is complicated, with critical interfaces. The most critical ones are:

- the temperature of the passive cooling/sorption cooler interface at V-groove 3. The heat lift of the sorption cooler depends steeply on this precool temperature (Fig. 11).
- the 4He-JT cooler helium precooling interface with the LVHX1 liquid reservoir of the sorption cooler. The heat lift of the 4He-JT cooler depends steeply on the cold-end temperature (Fig. 12). The precool temperature is also the dominant parameter for the heat load of the 4He-JT cooler.

Temperature fluctuations of the sorption cooler are driven by the variation of pressure with hydrogen concentration in the hydride beds throughout the desorption cycle, as well as by inhomogeneities in the properties of the six hydride beds. This leads to fluctuations of rather large amplitude at both the bed-to-bed
Fig. 11. Heat lift of the sorption cooler as a function of precool (V-groove 3) temperature.

Fig. 12. Heat lift of the $^4$He-JT cooler as a function of cold-end and precooling temperatures.

cycle frequency and the overall 6-bed cycle frequency. These are controlled at LVHX2 (§2.4.4), but not at LVHX1, the $^4$He-JT cooler interface. Temperature fluctuations in precooling the helium of the $^4$He-JT cooler are transferred to the cold head at 7–8 mK K$^{-1}$.

The active temperature regulation of the 4 K outer shell (§2.4.5) shields the lower temperature stages from temperature fluctuations coming from the warmer stages.

As long as the $^4$He-JT cooler precools the $^3$He and $^4$He gas below 4.7 K, the dilution cooler operates in its nominal configuration. It was found during CQM system tests that it can operate with a precool as high as 5 K, although this regime is expected to be rather unstable. The heat lift of the dilution cooler, proportional to the flow rate of the helium gases and to the square of the dilution cold head temperature, is not a critical parameter of the cooling chain, as the temperature can adjust at the expense of a weak loss in sensitivity. The flow rate is adjustable (§2.3.3), and can be chosen to ensure the required mission lifetime, possibly trading off bolometer temperature (thus instantaneous sensitivity) with lifetime.
The incoming $^3$He and $^4$He are precooled by the 4 K stage before JT expansion to 1.4 K. They flow to the dilution capillary through a standard counterflow heat exchanger with the outgoing $^4$He-$^3$He mixture. The passive and active cooling systems are highly interlinked and dependent on each other. Table 6 summarizes the principal dependencies.

The principal passive radiative and conductive heatflows and interfaces for Planck are shown in Fig. 13. The heat lift and loads from the coolers are not included. Expanded diagrams for LFI and HFI are shown in Figs. 14 and 15. Table 7 summarizes LFI heatflows.

3. Integration and test

3.1. Sorption cooler

An engineering model of the sorption cooler was built at JPL and tested with an engineering model of the cooler electronics built at the Laboratoire de Physique Subatomique et de Cosmologie in Grenoble (Pearson et al. 2007). A temperature-controlled mounting plate substituted for the warm radiator. All requirements were verified (Morgante et al. 2009).

The flight coolers were shipped fully assembled to avoid welding on the spacecraft or the use of demountable field joints to join the compressor the cold-end piping, and possible associated contamination. This had a substantial impact on the integration.

The thermal test program for the sorption coolers is summarized in Table 8. Subsystem testing was done by thermally simulating the main spacecraft interfaces and testing the flight allowable range for both interfaces. Requirements were met except for that on temperature fluctuations. Although it was recognized that the fluctuation requirement itself was a poor representation of the temperature stability required for good scientific performance (§ 2.3.1), a tiger team was formed to investigate the source of the fluctuations. The conclusion was that the excess fluctuations were gravitationally induced and were likely to be smaller in the micro-gravity space environment.

The interaction between the warm radiator and the compressor, and its impact on temperature fluctuations, could not be tested at subsystem level, nor could the performance of the V-grooves and sorption cooler piping be verified by subsystem testing.

Three higher-level tests were performed at the Centre Spatiale de Li`ege (CSL). In September 2005, an engineering model of the spacecraft and the payload were tested for the thermal performance of the cryo-chain and the V-groove system. An engineering model of the sorption cooler piping and cold-end were mounted to the three V-grooves and to an engineering model of the HFI instrument. The LFI instrument was thermally simulated using heaters. The sorption cooler compressor was simulated by high-pressure hydrogen gas bottles, a vacuum pump, and two pressure controllers to simulate the high and low pressure manifolds. This testing verified the thermal performance of the V-grooves with the heat loads from the sorption cooler.

In March 2006, the flight FM1 cooler was tested with the flight warm radiator. Only the first V-groove was mounted, and the important interface with the third V-groove was simulated thermally. For this test the sorption cooler was run at minimum and maximum power levels. The impacts of the warm radiator and compressor were found to be minimal. Requirements were met except (as in sub-system testing) for the temperature fluctuation requirement.

In July and August 2008 the flight FM2 cooler was tested with the full spacecraft and payload, again at minimum and maximum power. All requirements were verified.

3.2. $^4$He-JT and dilution coolers

An engineering model of the $^4$He-JT cooler was built at RAL using development models of the compressors. After testing at RAL, it was transported to IAS (Orsay), integrated with an engineering model of the dilution cooler system, and used to demonstrate the "4 K to 0.1 K" cryogenic concept. The performance of the two-cooler system and its dependence on the interface temperatures between the coolers was measured and was a key element in the definition of the cryogenic interface requirements between the JPL, RAL, and IAS teams.

A qualification model of the $^4$He-JT cooler was built and tested at RAL. In parallel, a qualification model of the HFI FPU was built, including a fully representative dilution cooler (including launch locks on the focal plane) and a reduced number of flight like bolometers (8). This qualification model of the FPU was tested in the Saturne 4 K test tank at IAS for function as well as for the performance of the bolometers, filters, and feed horns. The 18 K and 4 K interfaces of the FPU were provided by the 4 K Saturne cryostat. The radiation environment of the FPU was nearly a blackbody, the temperature of which could be changed from 2.7 K to 5 K.

In September 2005 a satellite system test was carried out at CSL with a thermal model of the service and payload modules, including the first V-groove and a simulator for the third V-groove, and the qualification model of the HFI including the $^4$He-JT cooler. The 18 K interface was provided by a sorption cooler cold head fed from pressurized hydrogen bottles.

The flight models were tested in Saturne in December 2007, and at CSL in the satellite level thermal test in July and August 2008. The CSL test was the first of the full Planck cryogenic chain. These tests showed that the sorption cooler precooling temperature was close to 17.5 K, that the $^4$He-JT cooling power margin at zero PID power was about 5 mW for a stroke amplitude $A_s$ of 3.5 mm (well below the maximum value of 4.4 mm), and that the cold end temperature was about 4.4 K, well below the maximum of 4.7 K required for the operation of the dilution cooler with reasonable margins. This showed that the system as built had significant margins, leaving a range of $\pm 2$ mW for temperature regulation of the 4 K stage.

During the CSL test instabilities developed when the 1.4 K stage was too cold. Liquid helium was overproduced and filled the pipes between the 1.4 K stage and the 4 K stage. Unstable evaporation then generated large temperature fluctuations.

Adjustment of the coolers for maximum cooling performance gives the best margins in operation of the cooling chain; however, because of such instabilities associated with excess liquid, the highest cooler performance does not necessarily lead to the optimum overall configuration. It is essential that the PID have enough power to warm the 1.4 and 4 K stages to the optimal operating point, far away from the unstable evaporation region.

Vibration from the compressors could affect the HFI data in several ways. No microphonic noise was seen in system tests when the vibration control system was activated in the drive electronics of the compressors; however, electromagnetic interference was seen in the qualification and flight model system tests at several beat frequencies of the compressor frequency and sampling frequency. In the FPU instrument tests with no $^3$He-JT cooler, the average amount of heat dissipated in the bolometer

4. Performance: Temperature

4.1. Temperatures, heat lift, and tuning in space

Radiative cooling began immediately after launch on 14 May 2009. Figure 16 shows the temperatures of the key elements as a function of time. The cooldown was completed on 3 July 2009 after a cool down in agreement with the ground tests and simulations. Active cooling from 20 K to 4 K was deliberately slowed down to allow calibration of the LFI.

4.1.1. Sorption cooler

The FM2 sorption cooler was activated on 2 June 2009 with the JT expander at a temperature of 90 K. Liquid hydrogen formed after 187 h, and the cooler transitioned to normal operating mode...
Fig. 13. Principal heatflows for Planck. Nearly 14 kW is incident on the solar panel, but less than 1 W reaches the FPU. Passive radiative cooling and thermal isolation are the keys to the overall thermal performance. Yellow arrows indicate radiation. White arrows indicate conduction.

9 h later. Initial tuning parameters were set close to those used during ground testing, except that the TSA set-point was lowered to minimize the heat load. Heat lift and temperature were similar to those in ground tests; however, temperature fluctuations were higher than those on the ground. Table 10 summarizes the results. As will be discussed later, the temperature fluctuations had no impact on the science data.

Due to degradation of the hydride with operation, the input power required to maintain the required heat lift increases with time. Figure 17 shows the high pressure and the desorption power as a function of time.

As discussed in §§ 2.4.3, the temperature of the warm radiator, the age of the hydride, and the temperatures of LVHX1 and LVHX2 are related. For the LFI, the set-point for the TSA at LVHX2 is set to a minimum to reduce the heat load on the sorption cooler. For the HFI, the temperature of LVHX1 must have margin to accommodate temperature drift.

The sorption cooler also affects the three V-groove temperatures, as the heat lifted from the focal plane is mostly radiated to space by the V-grooves. As TSA power is increased, the heat lifted by the sorption cooler increases, the load on V-groove 3 increases, and its temperature rises. Figure 18 shows the temperature of the heat exchanger on V-groove 3 (PC3C) and the power dissipated by the TSA as a function of time. The relationship is clear. In addition, there is a seasonal variation in the temperature of V-groove 3 driven by changes in Planck’s distance from the Sun. The closest approach to the Sun occurred on about the first of January; see also Fig. 37).

4.1.2. $^4$He-JT cooler

As seen in § 2.3.2, the performance of the $^4$He-JT cooler is characterised by the temperature $T_{JT.4K}$ of the JT and the maximum heat lift $H_{L_{max}}$ that the cooler can generate. While $H_{L_{max}}$ depends on both the high and low pressures of helium in the cooler, $T_{JT.4K}$ depends only on the low pressure. The operating characteristics of the $^4$He-JT cooler depend on three adjustable parameters and two environmental conditions:

- The stroke amplitude $\Delta S$.
- The compressor frequency $f_{\text{comp}}$. This can be chosen in the range 35–45 Hz. The choice is driven by four factors. First, the lowest resonance frequency of the spacecraft panel on which the compressors are mounted is 72 Hz, driving the choice above 37 Hz. Second, the operating efficiency shows a broad maximum around 40 Hz. Third, we want to minimize electromagnetic contamination and microphonic lines in the data. Fourth, in order to minimize mechanical stress, the frequency should be below 45 Hz. We chose 40.08 Hz as the nominal frequency.
- The filling pressure $P_{\text{fill}}$. This is adjustable only before flight. The filling pressure was 4.5 bar.
- The pre-cool temperature $T_{\text{pc}}$ provided by the sorption cooler. This temperature is at most 0.1 K higher than the LVHX1 cold head temperature and was found to be 17.3 K, thus in a range providing a large system margin.
- The temperature $T_{\text{comp}}$ of the base plate on which the compressors are mounted. This temperature is set by the spacecraft architecture and could not be tuned easily. The temperature in flight is 7°C and did not change by more than 1°C.

... during the nominal mission. This leads to negligible changes of performance during the mission.

We end up finally with one parameter adjustable in flight, the stroke amplitude $\Delta S$, and one environment parameter, the precooling temperature provided by the sorption cooler. The performance of the $^4$He-JT cooler as measured in flight is fully in line with the ground based tests given in § 2.3.2.

No extra heat load on the 4 K box was identified with respect to the CSL thermal balance/thermal vacuum test, showing that the launch had not affected the cryogenic configuration.

In flight the unstable evaporation of helium between 1.4 K and 4 K stages was seen but induces by the 4 K stage being too cold. The 1.4 K–4 K temperature plane was then mapped to find precisely the unstable zones which came out to be $T_{1.4 K} < 1.34 K$ and $T_{4 K} < 4.64 K$. The best operating region is $1.36 K < T_{1.4 K} < 1.4 K$ and $4.7 K < T_{4 K} < 4.75 K$. The operating point for flight was chosen in this zone.

During the CPV phase, $\Delta S$ was reduced to 3.45 mm in order to decrease the power of the $^4$He-JT cooler and optimise its operating conditions keeping the temperature above the unstable evaporation range. The vibration control system converged quickly to a new stable configuration, demonstrating that adjustment of this important subsystem would be easy should it be necessary. No further adjustment has been required.

The 4 K PID flight configuration has fixed power of 840 $\mu W$ on the redundant PID and regulating power of around 900 $\mu W$ on the nominal PID. The in-flight operating temperature of the...

\(^{a}\) Calibration and performance verification phase.

4 K cold tip is 4.37 K. The PID for the 4 K feed horn plate was set at 4.81 K.

4.1.3. Dilution cooler

The isotope flow was set to FNOM1 (Table 3) for the cooldown. The bolometer plate reached 93 mK and was still decreasing on 3 July 2009 when the flow was changed to Fmin2, the lowest available. The 1.4 K stage reached 1.23 K. The flow for a given restriction is slightly higher than it was during ground tests because the pressure regulators on the high pressure tanks had to be changed after a leak was found in the system test. The replacement regulators provide 19 bar rather than the original 18 bar.

The dilution is stabilized by a PID control with a power initially around 31 nW, providing a temperature near 101 mK. This power decreased slowly to a minimum of 24 nW in November 2010, and then began to rise again. This trend was expected, and is due to a small nonlinearity of the pressure regulators. The regulated pressure decreases slightly as the tank pressure drops to about half its initial value, then increases again as the tank pressures goes lower. The amplitude of the effect is fully consistent with the heat lift given in § 2.3.3.

The bolometer plate is stabilized at 102.8 mK with a PID power around 5 nW. The PID parameters give a very long time constant (about 0.5 h). This ensures that glitches induced by cosmic rays on the PID thermometer do not induce temperature fluctuations on the bolometer plate. Both PIDs show fluctuations on time scales of days to weeks, discussed in § 5.3.

The heat inputs on the bolometer plate are: (i) the input from the bias current of the bolometers (less than 1 nW); (ii) the microwave radiation reaching the bolometers (0.12 nW); (iii) cosmic rays that penetrate the FPU box and deposit energy in the bolometer plate (variable); (iv) the heat dissipated by microvibrations in the bolometer plate; and (v) heating from PID2.

The heat dissipated in the dilution and bolometer plates by micro-vibrations from the 4 K compressors was not measured precisely during ground tests but was of order 30 nW on the bolometer plate. Once during flight the \(^{4}\)He-JT cooler was turned off by the charge regulator that controls the current call from the drive electronics to the spacecraft. This single event allowed us to measure precisely the heat input from micro-vibrations from the compressors on the dilution plate. It was 26 nW. There was also evidence for a comparable amount of heat on the bolometer plate but it cannot be assessed accurately (the PID has a long time constant and reacted slowly as can be seen on the figure Fig. 19. The heat input from micro-vibrations is essentially constant.

Correlation of the bolometer plate temperature with both the Space Radiation Environment Monitor (SREM) data and the glitch rate on the bolometers on periods of days to weeks (§ 5.3)
shows that cosmic rays also heat the bolometer plate. The variable part of the power input from the cosmic rays can be calibrated using the PID response on long periods. This allows estimation of the total power input from cosmic rays, which was about 12 nW on the bolometer plate and 8 nW on the dilution plate for the first 100 days of the survey. These numbers could be checked using the small solar flare on 5–7 April 2010, and within uncertainties the powers agree. In January 2010 the increase of Solar activity brought these numbers slowly down by 1.5 and 1 nW respectively. There is thus a consistent picture in which the galactic cosmic rays detected by the SREM account for both the temperature fluctuations discussed in § 5.3 and the extra heating seen in flight on the bolometer and dilution plate.

In summary, the bolometer plate receives 10–12 nW (depending on the period) from cosmic rays and about 30 nW from the micro-vibration from the $^4$He-JT cooler. This agrees with the 40 nW obtained empirically from the gradients within the 100 mK stage. The dilution plate receives 26 nW from micro-vibration from the $^4$He-JT cooler and 7–8 nW from the cosmic rays, in very good agreement with the 35 nW obtained from the temperature gradients.

The heating by cosmic rays is higher than expected before flight by almost an order of magnitude. The period following the Planck launch was a period of exceptionally weak solar activity, resulting in very weak solar modulation of cosmic rays at 1 AU (Mewaldt et al. 2010) and references therein. They show that the flux of low energy (200 MeV/nucleon) nuclei from carbon to iron was four times higher than in the period 2001–2003, and 20% higher than in previous solar minima over the last 40 years. Nevertheless, the total flux of galactic cosmic ray protons, which dominates and peaks around 200 MeV, gives a total proton flux of $3 - 4 \times 10^3$ particles m$^{-2}$ sr$^{-1}$ s$^{-1}$ MeV$^{-1}$. 

---

**Fig. 17.** Sorption cooler high pressure and desorption power as a function of time.

**Fig. 18.** Temperature of the sorption cooler heat exchanger on V-groove 3 (PC3C) and TSA power as a function of time. The sorption cooler including the TSA is the dominant heat load on V-groove 3. As TSA power is increased, the heat lifted by the sorption cooler increases, the load on V-groove 3 increases, and its temperature rises. A smaller seasonal effect of the distance of Planck from the Sun is superimposed on this general trend. The closest approach to the Sun occurred at the beginning of January.
This accounts only for half the heating of the bolometer plate. The SREM total particle flux above 10 MeV is \(7 \times 10^3\) particles \(\text{m}^{-2} \text{s}^{-1} \text{sr}^{-1} \text{MeV}^{-1}\) depending on the effective acceptance solid angle of the SREM. This could indicate that the particles in the range 30–100 MeV, which can enter the FPU and have a high energy loss rate, contribute also to the bolometer plate heating. Note that this is the energy range of the so-called anomalous cosmic rays (neutral galactic atoms ionized and accelerated in the heliosphere and also strongly affected by the solar modulation).

In summary, the correlation between SREM data and PID power when applied to the total SREM count rate accounts well for the heating of the bolometer plate. The attempt to reconcile the SREM count rate with the galactic cosmic rays as well as modeling the heating of the plate from the galactic cosmic rays both fall short by nearly a factor of 2 indicating a possible significant contribution from the anomalous cosmic rays.

4.1.4. V-grooves, baffles, telescope

The primary and secondary telescope mirrors cooled after launch to 36.3 K and 39.6 K, respectively. The temperatures are quite stable, with a small annual variation driven by the distance of Planck from the Sun (Fig: 37).

The background (steady state) optical loading on the bolometers, \(P_{\text{opt}}\), was measured during the CPV phase in July 2009. From this, thermal emission in the HFI bands can be estimated. Several contributors to \(P_{\text{opt}}\) are well known from ground and flight calibration, including the in-band power \(P_{\text{CMB}}\) from the CMB, the thermal emission \(P_{\text{4K}}\) from the filter and horns at 4 K, and the thermal emission \(P_{\text{1.4K}}\) from the filters at 1.4 K (Planck HFI Core Team 2011a). \(P_{\text{opt}}\) is measured by the difference in apparent base temperature of the bolometers \(T_b\) without electrical bias (\(V_b = 0\)), the measured base temperature of the 0.1 K plate, and the thermal conductance \(G = g_0T^\beta\):

\[
P_{\text{opt}} = \frac{g_0}{\beta + 1} \left( T_{\text{B}}^{\beta+1} + T_0^{\beta+1} \right)
\]

The value of \(P_{\text{residual}} = P_{\text{opt}} - P_{\text{CMB}} - P_{\text{4K}} - P_{\text{1.4K}}\) is shown in Fig. 20 for the HFI bands. There is a clear trend of increasing \(P_{\text{residual}}\) with band center frequency. In the two highest frequency bands, the dependence of \(P_{\text{residual}}\) on frequency is stronger, as expected, since these bands are multimoded. In addition, the 857 GHz band has a contribution of sky signal from the galaxy that at the time of the tests was at least comparable to the error in \(P_{\text{residual}}\). The dominant sources of error in \(P_{\text{residual}}\) are a constant temperature offset in the 0.1 K plate, estimated to be \(\pm 1\) mK, due either to a calibration error in the thermometry or a gradient between the thermometer and bolometer locations, and an error in the value of \(g_0\) as determined from ground based measurements. For most bolometers, these errors are a few percent. However, for some bolometers, especially at 545 and 857 GHz, the optical loading produces a temperature rise in the detector of \(T_b - T_0\), comparable to the thermometer accuracy. Thus, error bars on the these points are > 100% as shown in Figure 20. The line through the data points is a least squares fit of the computed in-band power from the two mirrors multiplied by an emissivity, \(\epsilon\), independent of frequency. The best fit value of \(\epsilon < 0.07\%)\ is lower than the lowest preflight estimate for the mirror of 0.6%, shown by the dotted line in Fig. 20.

5. Performance: Temperature fluctuations

5.1. 17–20 K stage

Figures 21 and 22 show temperature as a function of time and the corresponding Fourier transforms for several LFI temperature sensors: LIVHX2, the sorption cooler cold end interface to the LFI where fluctuations arise; the TSA, where temperature is actively controlled; and the closest and farthest focal plane sensors from LIVHX2. Fig. 21 is for October 2009; Fig. 22 is for May 2010. The thermo-mechanical damping through the path going from the source of temperature fluctuations to the LFI radiometers is evident from the decrease in fluctuations with distance from LIVHX2. Damping increases with frequency, as expected. A maximum amplitude of a few millikelvin is obtained throughout the period; the cold end temperature drift, getting close to the TSA set-point, decreased the margin of power available for the control and produced an increase of the residual at the cooler low frequencies at the end of the year.

Temperatures of the HFI outer shield and LFI reference loads (Fig. 23) are relatively homogeneous and uniform throughout the year. Figs. 24 and 25 show temperature as a function of time and the corresponding Fourier transform amplitudes for two sensors from October 2009 and May 2010, respectively. Peaks at the sorption cooler frequencies are always below 1 mK amplitude, and at the microkelvin level in the region close to 70 GHz reference loads.

The temperature of the LFI backend unit (BEU, see Fig. 14) showed a 0.15 K daily modulation in the first part of the mission, driven by the transponder on-off cycle discussed in § 2.4.1. After the transponder was turned on continuously (OD 258), the temperature variation reduced dramatically (Fig. 26).

Table 11 gives typical daily mean temperatures and temperature variations of the LFI focal plane and backend during the first year of operations.

5.2. 1.4–5 K stages

The temperature of the 4 K box is regulated by a PID servo system with a heating belt on the 4 K box. The feedhorns that couple to the telescope are all at nearly the same temperature, which is controlled by four high sensitivity thermometers sampled at the same rate as the bolometers. Figure 27 shows the power spectrum of each of these thermometers over a broad range of frequencies. It can be seen that in the frequency range containing the scientific signal (above 16 mHz) the thermometer used for the regulation (PID4N) is basically within the very strict requirement set initially. The three others show fluctuations at about twice that level, which introduce additional noise of about 1/5 of the full detector chain noise. It also shows that the gradients on the 4 K plates are very low. This is comparable to the power spectrum temperature fluctuations observed in ground tests (Leroy et al. 2008).

The reference loads for the LFI 70 GHz radiometers are also mounted above the heater ring, and benefit from the same temperature stability. The 30 and 44 GHz reference loads are mounted below the ring. They are also protected from the fluctuations induced by the sorption cooler on the \(^{3}\)He-JT cooler but not as well as the 70 GHz loads. This is discussed in § 5.2.

An equivalent PID servo system controls the stability of the 1.4 K screen of the FPU using one of two redundant thermometers on the side of the 1.4 K stage structure. Two thermometers on the 1.4 K filter plate monitor its temperature with the same sampling as the detectors. Figure 28 shows the power spectrum
Fig. 19. Thermal behaviour of the 100 mK stage during the 4 K shutdown on 6 August 2009. The vibration level of the 4 K propagated to the dilution is measured from the step in the blue curve (signal of the active regulation of the dilution) after the rapid drop of the 4 K. It is equal to 26 nW.

of each of these thermometers over the same range of frequencies. They stay well below -10–30 times - the requirement of $28 \mu K \cdot Hz^{-1/2}$ (0.016–100 Hz) in the frequency range containing the scientific signal. The additional noise is typically smaller than 2% of the detector chain noise in line with ground measurements (Pajot et al. 2010).

In summary, these two stages behave exactly as designed and as tested on the ground. They do not add any significant noise to the measurements.

5.3. 0.1 K stage

In ground tests the natural fluctuations of the dilution cold head were essentially eliminated by PID control (low frequencies) and passive filtering (high frequencies). The PIDs on the dilution plate and bolometer plate inject variable but known heat inputs with average values of 28 and 5 nW, respectively. Fluctuations were basically within requirements during the ground tests Pajot et al. (2010), but perturbations from the test setting such as vibrations associated with helium transfer limited our ability to test very precisely this requirement.

In flight, the microwave radiation reaching the bolometers is variable but so small (0.12 nW) that it does not affect thermal behaviour.

In flight, cosmic rays above about 30 MeV penetrate the FPU box, causing glitches in the PID thermometers and depositing energy in the bolometer and dilution plates as discussed in § 4.1.3. The bolometer plate PID had to be set with long enough time constants that it did not generate temperature fluctuations from the glitch signals. As discussed in §§ 4.1.3 and 5.3.1, the flux of galactic cosmic rays is modulated by the solar wind. This is a significant variable heat source not present in ground tests.

Figure 31 shows the bolometer plate temperature and the corresponding power spectrum, for ground tests and in flight. The temperature data have been “deglitched” (cosmic ray hits producing a signal significantly larger than the noise have been detected and removed). It is clear that in the frequency range below 10 mHz there is an excess of fluctuations in flight with respect to ground testing but not affecting the science data. There is smaller excess in the 16–40 mHz range above the requirements and affecting the data. This noise component is not fully correlated across the bolometer plate.

5.4. Bolometer Plate—Particle Contribution

Big solar flares—typically 10 to 20 per solar cycle or at most three during the mission—are expected to heat the bolometer plate from 100 mK to 500 mK. This will create gaps in the survey of a few days. None has been seen in the nominal mission (and up to end 2010).

The particle flux on the satellite is monitored by the SREM as discussed in § 4.1.3. Although mainly aimed at monitoring solar particles during flares, it also detects galactic cosmic rays, which dominate in periods of low solar activity. Protons dominate (electrons are only 1% of the protons of a given energy and can be ignored). The protons are detected in the range 20–600 MeV, the range in which the energy deposited in matter is dominated by ionization. Figure 29 shows the excellent corre-
Planck Collaboration: The thermal performance of Planck

**Fig. 20.** Measured background power in the bolometer bands from the primary and secondary mirrors of the Planck telescope. The solid line through the data is a best fit of a constant emissivity, $\epsilon = 0.07\%$ times the computed blackbody power from the primary mirror at $\sim 36.2 \, \text{K}$ and the secondary mirror at $\sim 39.4 \, \text{K}$ in the measured bandpass for each detector. The upper solid line is the best case performance estimated before flight, which corresponds to a mirror with $\epsilon = 0.6\%$ at a temperature of $40 \, \text{K}$. The scatter in the measured power is largely due to uncertainty in gradients at the level $< 1 \, \text{mK}$ in the 100 mK plate.

**Fig. 21.** LFI temperatures, left, and corresponding spectra, right, in October 2009. Black: LVHX2; Blue: TSA, Red: TSR1 (focal plane sensor closest to LVHX2), Green: TSL6 (focal plane sensor farthest from LVHX2).

lation between the active regulation of the temperature of the bolometer plate and the SREM at frequencies between $10^{-7}$ and $10^{-5}$ Hz. Less strong (but present) is the correlation between the active regulation of the temperature of the dilution plate, which is also responding to slow changes in the flows of $^3\text{He}$ and $^4\text{He}$. If we subtract the two intrinsic sources of drift, we find a flat noise spectrum as expected from ground calibration, as shown in Fig. 30. This illustrates that all dominant sources of fluctuations of the 100 mK stage below a few $\times 10^{-5}$ Hz have been identified.

If we subtract the two intrinsic sources of drift, we find a flat noise spectrum as expected from ground calibration, as shown in Fig. 30. This illustrates that all dominant sources of fluctuations of the 100 mK stage below a few $\times 10^{-5}$ Hz have been identified.

If we subtract the two intrinsic sources of drift, we find a flat noise spectrum as expected from ground calibration, as shown in Fig. 30. This illustrates that all dominant sources of fluctuations of the 100 mK stage below a few $\times 10^{-5}$ Hz have been identified.

If we compare the noise spectra of the bolometer plate thermometer from ground calibration and in flight in the range of frequencies below $10^{-3}$ Hz (Fig. 31), we find consistency with ground calibrations as expected. This part of the spectrum probably has a large contribution from the intrinsic fluctuations of the dilution, which are not expected to change between ground and flight calibrations. This completes our understanding of the bolometer plate fluctuations down to this frequency. The difference between the curves (Fig. 30 left) in the frequency range 1–10 mHz, is at least partly due to the glitches from particles hitting the thermometers. After the contribution of the glitches is removed, the level of fluctuations is closer, but not fully consistent, with the level observed in ground calibration.
In summary, in flight, the 100 mK temperature fluctuations induced by the modulation of galactic cosmic rays dominate, but they do not affect the signal. In the frequency range between 16 mHz and 300 mHz, excess noise with respect to ground measurements is seen on the bolometers and thermometers. Furthermore any common thermal mode affecting all thermometers and bolometers that is not fully corrected by the bolometer plate PID is easily removed using the dark bolometer signals (see Planck HFI Core Team 2011b).

Showers of particles affecting more than 20 bolometers within a few milliseconds are also seen. (For fewer than 20 bolometers, the probability of physically unrelated but temporally correlated fluctuations becomes non negligible). Their arrival is followed by an increase in the temperature of the bolometer plate by up to 10 µK. The strongest showers occur at a rate of about one per day. Smaller temperature increases of order 0.01–0.1 µK occur at a rate of one per hour. These showers are likely to be induced by high energy particles interacting with parts of the payload, leaving energy in the bolometers and also in the 100 mK stage. The detailed physics of these events is not yet understood, but their phenomenological behaviour is well known. The temperature increases of the bolometer plate last up to one hour, in agreement with the time constant of the yttrium-holmium link to the dilution. The bolometer plate itself, coated with copper and gold, becomes isothermal in milliseconds. Fluctuations induced by these particles on the bolometer plate are therefore removed along with the other common modes. However, the bolometer housings have time constants relative to the bolometer plate of 1–2 s. The bolometers (and related housings) directly touched by the shower particles heat up suddenly, then cool down while the bolometers and housings untouched by the shower heat up under the influence of the bolometer plate. This induces for a short time interval of a few seconds a non-uniform thermal behaviour of the bolometer housings. This systematic effect is not yet treated in the pipeline used for the early papers and is not a dominant effect. It is still one of the
**Fig. 24.** Daily behaviour of temperatures in the HFI outer shield in October 2009, left, and corresponding Fourier transform amplitude, right. Black: 4KL1 sensor (close to 30 and 44 GHz loads); Blue: PIDN sensor (close to 70 GHz loads).

**Fig. 25.** Daily behaviour of temperatures in the HFI outer shield in May 2010, left, and corresponding Fourier transform amplitude, right. Black: 4KL1 sensor (close to 30 and 44 GHz loads); Blue: PIDN sensor (close to 70 GHz loads).

**Fig. 26.** Left plot: LFI backend temperatures (black: Left BEM1 sensor, blue: Left BEM2 sensor, red: Right BEM1 sensor, green: Right BEM2 sensor) around operational day (OD) 258 of flight operations, when the transition to an always-on condition for the transponder was implemented. Right plot: comparison of the Fourier transform amplitude of the Left BEM1 sensor before (black) and after (blue) transition to stable, showing the daily time scale peaks disappearing.
Table 11. Mean values and daily stability of the main LFI temperature sensors in two cases representative of the best and worst case. The early phase was the best case for the focal plane and the worst case for the backend; the late phase was the opposite.

a “Early Phase” means sorption cooler FM2 operating, transponder cycling. “Late Phase” means sorption cooler FM1 operating, transponder always on.

Fig. 27. Power spectrum of thermal fluctuations measured at the feedhorns that couple to the telescope.

5.5. Transients, cooldown timescale

At the end of the CPV phase a set of tests were performed to characterize the timescales and propagation of thermal fluctuations, as well as the response of the radiometers to changes in temperature.

The dynamic response of the LFI focal plane to turning off the TSA was measured, along with the transfer functions
**Fig. 28.** Power spectrum of thermal fluctuations measured at the 1.4 K filter plate.

**Fig. 29.** Correlation between the signal of the SREM (in red) and the inverse signal of the active regulation of the temperature of the plate stage (in green) for the frequency range $10^{-7} - 10^{-5}$ Hz. The signal of the active regulation of the dilution plate is shown in blue.
between the various thermal sensors in the LFI focal plane. Figure 32 shows the locations of the sensors. Figure 33 shows the response of the system when the TSA is turned off.

The focal plane temperature is quite stable over time (Fig. 34), showing a long term drift caused by the orbital variation in the Earth’s distance from the Sun. Starting at about day 350, changes in the TSA control set-point were needed in order to keep the stability within acceptable limits.

The temperature of the LFI backend unit, mounted in the SVM, was much less stable, showing a strong daily variation driven by the transponder. As described in § 2.4.1, the solution was to keep the transponder on continuously; in the second part of the first year of operations the only residual effect was the common SVM seasonal drift, with some further discontinuity related with major sorption cooler operations (Fig. 35).

The LFI reference loads (Valenziano et al. 2009) are thermally connected to the HFI outer shield. Temperature fluctuations in the lower part of the shield are transmitted to the 30 and 44 GHz reference targets. Temperature fluctuations in the upper part of the shield are almost entirely damped by the PID controls (§ 2.4.5). The temperature shows a 1 mK peak-to-peak fluctuation amplitude at the typical time scales of the sorption cooler and the overall seasonal drift (Fig. 36).

5.6. Seasonal effects

The dominant seasonal effect comes from the annual variation in the distance of Planck from the Sun. Figure 37 shows the temperatures of the solar array, VG3, and the primary mirror for about 500 days starting 22 June 2009 (i.e., during the initial cooldown).

5.7. Interactions between systems and instruments

5.7.1. Behavior of liquid hydrogen at 20 K

Temperature and temperature fluctuations are shown for two different regimes in the cold end. On the left side of Fig. 38, the fluctuations are much “cleaner” than on the right side, i.e., with
Planck Collaboration: The thermal performance of Planck

Fig. 32. Location of temperature sensors in the LFI focal plane.

Fig. 33. Dynamic behaviour of the sensors when TSA control is switched off at roughly 76 000 s. Fluctuations at 1 mHz are reduced more than 40%, revealing longer-term fluctuations caused by the cycling of the sorption cooler.
lower fluctuation levels especially at high frequencies. This behavior is well understood and was observed during ground testing. The cold-end, in the left regime, is in a balanced state (heat lift = power dissipation) where the liquid interface is drawn into the LVHX2 body. In contrast, the cold end in the right regime is in an unbalanced state (heat lift > power dissipation) in which excess liquid forms. The increased fluctuations are due to plug-flow events as the liquid interface moves into the counter-flow heat exchanger just past the LVHX2 body.

5.7.2. Behavior of liquid helium at 4 K and 1.4 K

Liquid $^4$He is generated at the 4 K precool and at the 1.4 K JT. Instabilities developed during the CQM CSL test (§3.2) when the 1.4 K stage was too cold, and in flight when the 4 K stage was
 Fig. 36. Temperature curve of the HFI L1 sensor close to 30 GHz reference load, since the beginning of the first sky survey up to OD 389.

too cold (§ 4.1.2). As discussed earlier, liquid helium was over-produced and filled the pipes between the 1.4 K stage and the 4 K stage, and unstable evaporation then generated large temperature fluctuations including the 100 mK stage. It is interesting that adjustment of the coolers for maximum cooling performance, which gives the best margins in operation of the cooling chain, does not necessarily lead to the best configuration because of instabilities associated with excess liquid helium. It was essential for Planck that the PIDs have enough power to warm both the 1.4 and 4 K stages to the optimal operating point far away from the unstable evaporation region, even with the lowest isotope flow for the dilution.

6. Operations

Adjustments to the sorption cooler are necessary throughout the mission due to the gradual loss of hydrogen-absorbing capacity of the compressor hydride material (Borders et al. 2007) with cycling and time at high temperature. As the hydride degrades, the input power is increased while the cycle-time is decreased. In terms of degradation, it is ultimately the input power that limits the sorption cooler lifetime, as both the desorption and heatup channels are limited to 250 W each. Adjustments are made as needed on a weekly schedule, based on analysis of pressures and temperatures of the compressor elements and the various heat exchangers.

The HFI cryochain parameters are set once for the entire mission. HFI operations essentially consist in monitoring the housekeeping parameters during the daily telecommunication periods. The only moving part of the satellite payload is the $^4$He-JT cooler compressor, so its stroke amplitude, head temperature, and currents, transducers, high and low gas pressures, and flow rates are monitored carefully. Dilution cooler helium pressures and temperatures are monitored. In particular, the helium remaining in the tanks, which determines the HFI lifetime, is monitored via temperature, pressure, and flow rate sensors along the dilution cooler pipes. The power put on the various PIDs (at the 4 K box, 1.4 K filters, dilution plate, and bolometer plate stages) is monitored as well. As a side effect, this allows detection of solar flares through their heating effect on the bolometer plate. Finally all temperature sensors at the different subsystems are closely monitored.

7. Lessons learned for future missions, and conclusion

The Planck thermal system combines passive radiative cooling and thermal isolation with three mechanical coolers, two representing new technologies used for the first time to cool scientific instruments in space, in an elegant overall thermal design. The system works as designed, and it works very well, delivering the thermal environment required by Planck’s state-of-the-art instruments.

We conclude here with some “lessons learned,” many incorporated in Planck, which we hope will be useful for future missions. Some may seem obvious in retrospect; however, trade-offs must be made during construction without full knowledge of the consequences, and prior experience is an invaluable guide.

– In cryogenic missions with stringent temperature stability requirements, temperature sensors on the spacecraft (SVM) and telescope should have an accuracy significantly better than on Planck (typically 0.1 K resolution).
– The design and lifetime of the sorption cooler gas-gap can affect the power requirements and lifetime of the sorption cooler. Additional margin in this area would have been helpful at little cost to the mass of the system.
– Temperature stability requirements in the spacecraft should be specified for all components and “panels” not according to their own operating requirements, but rather for their effect on the thermal stability of the cryogenic system.
– The initial definition of the margins in a long cryogenic chain such as Planck’s leads to overspecification if many new systems are considered for which performance is not yet well...
Fig. 37. Seasonal variation in the temperature of the solar panel (top), V-groove 3 (middle), and the primary mirror (bottom). Individual readings are shown for multiple temperature sensors on each part of the structure (left, all three panels). Quantization effects are clearly visible for V-groove 3 and the primary mirror. These are reduced but not eliminated by averaging the relevant sensors (black line in all three panels).
established. When each stage works nominally the system ends up with a large margin. It would be better to stretch the range in which the coolers work if possible rather than to add an additional stage.

- Excess cooling capacity provides margin in the operation of the cryo chain, but can lead to decreased stability by unstable evaporation of excess cryogenic fluids (helium or hydrogen). Enough adjustment of cooling and PID power is needed to cope with the configuration where all coolers are at their best performance.

- Tests of cryogenic space systems are long and expensive. Precooling loops like the one installed in the dilution cooler to shorten the cooldown time in tests can have serious drawbacks if they become failure hazards (it is difficult to remove the helium in the loop and test it). Heat switches are another mechanism to optimize cooldown time, but they require heat input at the lower temperature end decreasing the heat lift of the corresponding cooler. This is a draw back which has to be taken into account (see next point).

- The system definition should consider carefully not only the margins for the planned operating point, but also margins along the entire cooldown “path.” Coolers have little power when they are far from their optimal operating temperature, and the system could be stuck at a temperature well above the one at which it can operate. The Planck 4He-JT cooler, for example, had its minimum margin when starting to cool down from 20 K, when the heat switch to lower stages was turned on.

- Sub-kelvin stages have been found on Planck to be, as expected, very sensitive to heat input by microvibration from mechanical compressors (there is no other source of microvibrations on Planck). It has not been possible to determine precisely the frequency range responsible for the heating.

- An end-to-end thermal model is necessary, but that does not imply making a single unified model containing the full complexity of all stages. Such a model would be very complicated. Detailed modelling of subsystems that gave empirical interface models to be used in a global model was the philosophy used in Planck, and it worked well.

The Planck thermal architecture is the first implementation in space of a combination of active and passive cooling for a CMB mission. The architecture allows the simultaneous cooling of the HFI bolometers to 0.1 K and the LFI radiometers to 20 K, thereby enabling unprecedented instrument sensitivity. The thermal system has operated successfully to date and is expected to continue to perform beyond the nominal mission duration. Thermal fluctuations are present in the various temperature stages, particularly near 20 K, but these have not compromised the systematic error budget of the instruments. The wide range of scientific discovery enabled by Planck including its unique thermal architecture, is evidenced by the accompanying papers describing early scientific results.

8. Acknowledgments

We acknowledge the use of thermal models from Thales for the payload, IAS for the HFI, JPL for the sorption cooler, and Laben for the LFI. The HFI team wishes to thank warmly the Herschel Planck project team under the leadership of Thomas Passvogel for their time, effort, and competence in solving the crises following failures of several parts of the cryo chain during Planck system tests. We acknowledge very useful discussions on the thermal behaviour of Planck during the system tests from the CSL team, who went far beyond their formal responsibilities.
