Abstract—A high efficient planar integrated magnetics (PIM) design approach for primary-parallel isolated boost converters is presented. All magnetic components in the converter including two input inductors and two transformers with primary-parallel and secondary-series windings are integrated into an E-I-E core geometry, reducing the total ferrite volume and core loss. The transformer windings are symmetrically distributed into the outer legs of E-cores and the inductor windings are wound on the center legs of E-cores with air gaps. Therefore, the inductor and the transformer can be operated independently. Due to the low reluctance path provided by the shared I-core, the two input inductors can be integrated independently, and also the two transformers can be partially coupled each other. Detailed characteristics of the integrated structure have been studied in this paper. AC losses in the windings and the leakage inductance of the transformer are kept low by interleaving the primary and secondary turns of the transformers substantially. Because of the combination of inductors and transformers, maximum output power capability of the fully integrated module needs to be investigated. Winding loss, core loss and switching loss of MOSFETs are analyzed in-depth in this work as well. To verify the validity of the design approach, a 2-kW prototype converter with two primary power stages is implemented for a fuel cell fed traction applications with 20-50 V input and 400-V output. An efficiency of 95.9% can be achieved during 1.5-kW nominal operating conditions. Experimental comparisons between the PIM module and three separated cases have illustrated the PIM module has advantages of lower footprint and higher efficiencies.

Index Terms— Core loss, dc-dc converter, fuel cell, inductor, isolated boost, planar integrated magnetics (PIM), transformer and winding loss.

I. INTRODUCTION

DISTRIBUTED generation systems, back-up systems or traction systems based on fuel cells or batteries, requires high-power high-gain dc-dc converters to boost the low source voltage (20-50 V) to a higher dc-link voltage (350-400 V). For safety or EMC reasons, transformer isolation is often required or preferred. As power levels increase, input currents quickly reach levels where paralleling of primary switches becomes necessary. Since transistors are often operated close to their maximum drain current rating, direct paralleling of MOSFETs may require screening and parameter matching of on-resistance, gain and/or threshold voltages. Slowing switching speed by increasing gate impedance or addition of source inductance may also be required. A new, simple and low cost method to extend power level in isolated boost converters by paralleling of critical high-
distributed magnetics becomes promising. In this paper, a new approach to integrate the distributed magnetics components for the primary-parallel isolated boost converter is presented. All magnetic components in the converter including the two input inductors and two transformers with primary-parallel and secondary-series connected windings are integrated into an E-I-E core geometry, reducing the total ferrite volume and core loss. The transformer windings are symmetrically distributed into the outer legs of E-cores and the inductor windings are wound on the center legs of E-cores with air gaps. Detail characteristics of the integrated structure are presented in Section III. Due to the integration of inductors and transformers, maximum output power capability of the integrated module has to be considered to avoid flux saturation in the core. Core loss estimation for the PIM structure has been investigated in-depth and an effect of core loss under dc bias operation has been considered as well. AC losses in the windings and leakage inductance of the transformers are kept low by interleaving the primary and secondary turns of the transformers. A detailed power loss analysis is given in section V. To verify the validity of the design approach, a 2-kW prototype converter with two primary power stages is implemented for fuel cell fed traction applications with 20~50-V input and 400-V output. An efficiency of 95.9% can be achieved during 1.5-kW nominal operating conditions. Experimental comparisons are presented in section VI show the advantages of low profile and high efficiency for the PIM module. In addition, the proposed PIM approach can solve the start-up problem of the boost converter without adding external Flyback winding [23].

II. PRIMARY-PARALLEL ISOLATED BOOST CONVERTER

Boost derived topologies are preferred in fuel cell applications due to their low input current ripple [24]. Fig.1 shows a primary-parallel isolated boost derived topology suitable for handling high input currents for fuel cell applications. Series connection of transformer secondary windings ensures current sharing during energy transfer cycle when power is transferred to output. In this topology, primary power stages share the same control signals with same phase switching sequence for the corresponding switches which allows a simpler control. Output rectification unit as well as input and output filters are common to both of the primary stages. The paralleling method splits the critical primary high-ac-current-loop into two smaller loops. Each of the smaller loops only needs to switch half of the input current thereby achieving much faster current switching and thus higher conversion efficiency. Since the two transformers $T_1$ and $T_2$ share input current and power level, a higher turns ratio transformer in the conventional full-bridge isolated boost converter can be replaced by two individual transformers with lower turns ratio which allows a simpler design and manufacturing of the transformers.
Since the two primary stages operate synchronously utilizing the same control signals, a single stage is analyzed as follows. Fig.2 shows basic waveforms of the primary-parallel isolated boost converter. Primary switches, \(S_1-S_6\), are hard switched and operated in pairs, \(S_1-S_3\) and \(S_4-S_6\) respectively. Driving signals are 180° phase shifted. Switch transistor duty cycle, \(D\), is above 50% to ensure switch overlap and thus a continuous current path for the boost inductor current. The basic converter operation can be divided into four stages [24].

1) Stage 1 (T₁): All switches, \(S_1-S_6\), are on and the inductor is charged. All rectifier diodes, \(D_1-D_4\), are off and current in the transformer secondary winding is zero.

2) Stage 2 (T₂): The first energy transfer period, \(T₂\), starts when switches, \(S_1\) and \(S_2\), are turned off. Inductor energy discharges with its current flowing through primary switch, \(S_1-S_3\), and transformer, \(T_1\) primary. The current in the secondary side flows through the rectifier diodes, \(D_1-D_2\), and the output capacitor, \(C\).

3) Stage 3 (T₃): Works the same as stage 1. All switches are turned on, the inductor is charged and the inductor current, \(i_{L₁}\), increases linearly;

4) Stage 4 (T₄): The second energy transfer cycle, \(T₄\), starts when switches, \(S_1\) and \(S_2\), are turned off. Inductor energy discharges with its current flowing through primary switches, \(S_1-S_3\), transformer, \(T_1\) primary. The current in the secondary side flows through the rectifier diodes, \(D₃\) and \(D₄\), and the output capacitor, \(C\).

---

**III. MODELING OF INTEGRATED MAGNETICS**

Two separated transformers and one boost inductor are integrated into an E-I-E core geometry for hybrid dc-dc converter in [25]. In this study, an additional inductor is added into a combined E-I-E core geometry where two independent transformers, \(T_1\) and \(T_2\), and two boost inductors, \(L_1\) and \(L_2\), are integrated. Fig.3 shows the proposed integrated magnetics structure. The windings of each transformer are symmetrically distributed into the outer legs of the two E-cores. \(L_1\) and \(L_2\) are wound on the center legs of E-cores with air gaps. The middle I-core provides a low reluctance return path where a complete flux cancellation can be achieved since the two transformers, \(T_1\) and \(T_2\), operate with in-phase currents utilizing the same control signals. In fact, the shared I-core could be removed where E-I-E geometry becomes E-E geometry since zero flux is in the shared I-core. However, the two inductors, \(L_1\) and \(L_2\), will be fully direct coupled if the shared I-core is removed. This results in a huge spike of inductor current at commutation point if there is any small mismatch in two primary stages [26]. Accordingly, the effect of the shared I-core is to decouple the two inductors. The flux generated by the transformer windings circulate only through the outer legs of the E-cores, which does not affect the inductor’s behavior. As shown in Fig.3, flux \(\Phi\) (include dc component) generated by the two input inductor windings goes through the two E-cores, and no dc flux exists in the shared I-core due to the cancellation. As seen in Fig.3, at a certain time period, half of \(\Phi_1\) increases the total flux in the right leg together with \(\Phi_2\) and \(\Phi_3\), and the other half of \(\Phi_1\) decreases it in the left side. A reverse situation will occur during the next time period. As a result, \(\Phi_1\) will not affect transformer’s behavior. Hereby, the transformers and the inductors are not coupled electromagnetically although the windings are wound in the same core. The flux waveforms in each leg are presented in Fig.9. The proposed structure features an uncoupled technique for all magnetic components in the primary-parallel converter, and there may not have other possible configuration unless using the customer design core geometries instead of the standard core geometries.

Fig.3 shows an equivalent magnetic reluctance model of the PM module where \(R_1\) is the reluctance of the outer leg of E-core, \(R_2\) is the reluctance of I-core and \(R_c\) represents the reluctance of the center leg of E-core. \(R_c\) is much bigger than \(R_1\) and \(R_2\) due to the air gaps in the center legs. Since the transformers and the inductors are not coupled electromagnetically, the equivalent magnetic model can be divided into two parts as shown in the bottom of Fig.4. The left figure represents the magnetic model associated with \(T_1\) and \(T_2\). The flux \(\Phi_1\) and \(\Phi_2\) does not flow in the center legs of the E-core. The flux \(\Phi_1\) is identical to the flux \(\Phi_2\) due to two transformers operate with in-phase currents utilizing the same control signals. Therefore, the flux \(\Phi_1\) and \(\Phi_2\) in the shared I-core are fully cancelled. The right figure represents the magnetic model of the two inductors, \(L_1\) and \(L_2\).

With the assumption that the leakage flux through the air and the fringing effect are negligible, equations (1) ~ (3) can be derived according to the magnetic model,

\[
N_1 \cdot i_{m_1} = \Phi_1 \cdot (2R_1 + R_2) + (\Phi_1 - \Phi_2) \cdot R_2 
\]

\[
N_2 \cdot i_{m_2} = \Phi_2 \cdot (2R_1 + R_2) + (\Phi_2 - \Phi_4) \cdot R_2 
\]

\[
2 \cdot N_1 \cdot i_L = 2 \cdot \Phi_3 \cdot R_c + 0.5 \cdot \Phi_3 \cdot (2R_1 + R_2) 
\]

where \(N_1\) and \(N_2\) are the number of primary turns for the transformers \(T_1\) and \(T_2\) respectively. \(N_1\) is the number of turns for
the inductors $L_1$ or $L_2$. The rate of change on $\Phi_1$ and $\Phi_2$ are the same over the entire period. Based on the Faraday’s law, magnetizing inductances can be obtained,

$$L_{m1} = \frac{N_1^2}{2R_1 + R_2}$$

(4)

$$L_{m2} = \frac{N_2^2}{2R_1 + R_2}$$

(5)

$$L_1 = L_2 = \frac{2 \cdot N_L^2}{2 \cdot R_c + R_1 + 0.5 \cdot R_2}$$

(6)

For a single separated transformer with the same winding arrangement at the outer leg, the magnetizing inductance is equal to, $L_{m} = N^2 / 2(R_1+R_2)$, where $N$ is the number of primary turns for the single transformer. It is important to note that the integrated transformers have higher magnetizing inductances than the single case when both $T_1$ and $T_2$ have same current excitation. This is due to the fact that the mutual inductance between the two transformers $T_1$ and $T_2$ increases the magnetizing inductance. The coupling effect between $T_1$ and $T_2$ is shown in appendix.

IV. MAGNETICS DESIGN CONSIDERATION

The advantages of this structure are highlighted in [27]. Table-I has shown the integrated module has advantages in the cost, the efficiency, the size and the manufacturability at expense of the design process. Another drawback of the PIM module is to limit the maximum output power capability due to the overlapped flux. According to Faraday’s law and Ampere’s law, the peak flux densities of each magnetic component in the PIM module can be derived,

$$\hat{B}_T = \frac{V_{out} \cdot (1 - D)}{4 \cdot n \cdot f \cdot N \cdot A_e}$$

(7)

$$\hat{B}_L = \frac{\mu_0 \cdot N_L \cdot I_{pk}}{l_g}$$

(8)

$$\hat{B}_{Lac} = \frac{\mu_0 \cdot N_L \cdot \Delta I}{2 \cdot l_g}$$

(9)

where the peak current for the inductor is,

$$I_{pk} = I_{dc} + \frac{\Delta i}{2} = -\frac{P_0}{\eta \cdot V_{in}} + \frac{V_{in} \cdot (D - 0.5) \cdot l_g}{2 \cdot f \cdot \mu_0 \cdot N_L^2 \cdot A_e}$$

(10)
\(B_T\) and \(B_L\) represent the peak flux density of each transformer (\(T_1\) or \(T_2\)) and inductor (\(L_1\) or \(L_2\)) respectively. \(B_{lac}\) is the peak flux density of ac component of each inductor as shown in Fig. 9. The same number of primary turns for the two transformers, \(N_1 = N_2 = N\), is assumed.

\[D\] is the switching duty cycle, \(n\) is the turns ratio of transformers, \(f\) is the switching frequency, \(A_e\) is the cross-section of the outer leg of E-core, \(l_g\) is the length of air gap in each center leg, \(P_o\) is the output power, \(\eta\) is the efficiency of the converter, \(\mu_0\) is the permeability of air and \(V_{in}\) represents the input voltage. In order to avoid flux saturation in the PIM module, the following equations are required,

\[
B_T + B_L = \frac{V_{out} \cdot (1 - D)}{4 \cdot n \cdot f \cdot N \cdot A_e} + \frac{\mu_0 \cdot N_L \cdot P_o}{\eta \cdot V_{in} \cdot l_g} + \frac{V_{in} \cdot (D - 0.5)}{2 \cdot f \cdot N_e \cdot A_e} \\
\leq B_{sat}
\]

(11)

The 3D graph in Fig.5 shows the relationship among the output power \(P_o\), the number of turns of primary winding \(N_p\), and the number of turns of inductor winding \(N_L\) which has been plotted based on (11) with 100 kHz switching frequency and 0.5 mm airgap. In order to design a 2-kW PIM module, the number of inductor turns, \(N_L\), cannot exceed 3 turns. Its 2D relationship of \(N_p\) and \(N_L\) corresponding to the maximum output power capabilities is illustrated in Fig.6. The maximum output power can be enhanced by increasing the number of primary turns \(N\) or decreasing the number of inductor turns \(N_L\). Fig.7 illustrates the fact that maximum output power capability of the PIM module is decreased by reducing the switching frequency. Of course, more energy can be stored by using large airgap, resulting in a large output power capability for the PIM module as illustrated in Fig.8. However, a large airgap results in a low inductance which causes a high current ripple in the circuit for the same number of turns and thereby reduces the efficiency. Moreover, a larger

winding loss will be induced due to the fringing effect. Although the maximum output power can also be increased by using higher number of turns of primary winding $N$, larger winding losses and leakage inductances of the transformers $T_1$ and $T_2$ will be produced, reducing the efficiency as well. Unavoidable tradeoff in the power loss exists in the PIM design and the detailed power losses analysis will be given in section V.

V. POWER LOSS ANALYSIS

A. Core Loss

Core loss separation approach [28] assumes that three fundamental effects are contributing to core losses: static hysteresis loss, eddy current loss and excess eddy current loss. The approach of loss separation has a practical disadvantage: such models are based on parameters, which are not always available and difficult to extract. The most commonly used equation that characterizes core losses is the Steinmetz equation (SE), a curve-fitting expression of measured data under sinusoidal excitation.

$$P_v = k \cdot f^\alpha \cdot (\frac{\Delta B}{2})^\beta$$

(12)

where $k$, $\alpha$, $\beta$ are material parameters, $\Delta B$ is peak-to-peak flux density of a sinusoidal excitation with switching frequency $f$, $P_v$ is time-average core loss per unit volume. Unfortunately, the Steinmetz equation is only valid for sinusoidal excitation. This is a significant drawback since in power electronics applications the core material is normally exposed to non-sinusoidal flux waveforms. Core loss due to non-sinusoidal waveforms can far exceed the loss due to sinusoidal waveforms, even if the frequencies and the peak-to-peak flux densities are identical [29]. In order to determine losses for a wider variety of waveforms, some modified expressions including modified Steinmetz expression (MSE) [30], generalized Steinmetz equation (GSE) [31], improved GSE (IGSE) [32], improved IGSE (I\(^2\)GSE) [33], natural Steinmetz extension (NSE) [34], equivalent elliptical loop (EEL) [35] and waveform coefficient Steinmetz equation (WCSE) [36] were introduced. A complete comparison among these modified empirical methods shows that the IGSE have the best loss determination with a wide variety of waveforms [29].

$$P_v = \frac{1}{T} \int_0^T k_i \int \left[ \frac{dB(t)}{dt} \right]^\alpha \cdot \Delta B^{\beta-\alpha} \cdot dt$$

(13)

where,

$$k_i = \frac{k}{(2\pi)^{\alpha-1} \cdot \int_0^{2\pi} |\cos \theta|^\alpha \cdot 2^{\beta-\alpha} \cdot d\theta}$$

(13) shows the IGSE expression where $k$, $\alpha$ and $\beta$ are the same parameters used in the Steinmetz equation (12). The angle $\theta$ represents the phase angle of the sinusoidal waveform. Applying a piecewise linear model (PWL) to any waveform and then combining with the IGSE, leads to an easy-to-use expression for accurate calculation of losses with any flux waveform, without requiring extra characterization of material parameters beyond the parameters of the Steinmetz equation.

It is necessary to know the flux density waveforms to estimate core loss properly using IGSE. Fig.9 shows the flux density waveforms in each leg of the PIM module.

1) In the time period $t_0$-$t_1$, the transformer flux $\Phi_T$ and the inductor flux $\Phi_L$ are adding together in the left side legs of both E-cores. On the other hand, they are cancelling in the right side legs.

2) During the time period $t_1$-$t_2$, the rate of change of $\Phi_T$ is zero, and therefore ac flux $\Delta B_2$ in the two side legs are identical to ac flux on the inductor $\Delta B_L$.

3) $t_2$-$t_3$, is the opposite of the period $t_0$-$t_1$, where the transformer flux $\Phi_T$ and the inductor flux $\Phi_L$ are opposing in the left side legs of both E-cores. Meanwhile, they are added in the
right side legs. 

4) $t_{r-t_e}$ is the same as $t_{r-t_e}$. The red dashed lines shown in Fig.9 (a) and Fig.9 (b) represent the overall flux density waveforms in the two side legs respectively. Since the flux of transformer $\Phi_2$ does not go through the center leg, the overall flux density waveform in the center leg is only dependent on the flux of inductor $\Phi_L$.

The core loss can be calculated individually for each leg. For the applied flux waveform as illustrated in Fig.9, by using (13) together with PWL method, the following equations of core loss for each leg is obtained,

$$P_{vs} = k_i \cdot f^\alpha \cdot \left[ (\Delta B_1^\beta + \Delta B_2^\beta) \cdot (1 - D)^{1-\alpha} + 2 \cdot \Delta B_2^\beta \cdot (D - 0.5)^{1-\alpha} \right]$$

$$P_{pc} = 4 \cdot k_i \cdot f^\alpha \cdot \Delta B_2^\beta \cdot (D - 0.5)^{1-\alpha}$$

where,

$$\Delta B_1 = 2 \cdot (B_T + B_{lac})$$

$$\Delta B_2 = 2 \cdot B_{lac}$$

$$\Delta B_3 = \Delta B_1 - \Delta B_2 = 2 \cdot (B_T - B_{lac})$$

and $P_{vs}$ is the core loss per unit volume in each side leg and $P_{pc}$ is the core loss per unit volume in the center leg. The flux $\Phi_1$ is identical to the flux $\Phi_2$ due to two transformers operating with in-phase currents utilizing the same control signals. The two flux $\Phi_1$ and $\Phi_2$ are fully cancelled in the shared I-core where zero core loss ideally can be achieved. Table II shows the calculated results of core loss in each leg with different input voltages. The worst case for the core loss is in high input voltage where a higher peak flux is induced. In order to illustrate the inaccuracy of SE with (12), Table III shows an error analysis between SE and IGSE for the core loss of the PIM module.

However, the aforementioned calculations are based on the IGSE formula which neglects the fact that core losses vary under dc bias conditions, i.e. the Steinmetz parameters change under dc bias condition. When a core operates under dc bias condition, the core loss still can be described using the Steinmetz equation (12) or the IGSE (13). However, the Steinmetz parameters must be adjusted according to the dc bias present. Pre-magnetization $H_{DC}$ causes changes in the Steinmetz parameters $\beta$ and $k$, but not in the parameter $\alpha$. For many materials, the impact of a dc bias cannot be neglected as it may increase the core loss by a factor of more than two [37]. According to Steinmetz Pre-magnetization Graph (SPG) of the material ferrite N87 in [37], the core losses in this converter under different dc bias can be approximately estimated by multiplying the coefficient of SPG. The results are shown in Table VI and Table VII respectively.

### B. Winding Loss

Winding losses in transformers increase dramatically with high frequency due to eddy current effects. Eddy current losses, including skin effect and proximity effect losses seriously impair the performance of transformers in high-frequency power conversion applications. Both the skin effect and the proximity effect cause the current density to be non-uniformly distributed in the cross-section of the conductor, and thus cause a higher winding resistance at higher frequency. The most commonly used equation that characterizes winding losses is the Dowell’s equation [38]-[40],

$$R_{dc,m} = \frac{\varepsilon}{2} \cdot \frac{\text{sin} \varepsilon + \text{sin} \varepsilon}{\text{cosh} \varepsilon - \text{cos} \varepsilon} + (2m - 1)^2 \cdot \frac{\text{sin} \varepsilon - \text{sin} \varepsilon}{\text{cosh} \varepsilon + \text{cos} \varepsilon}$$

where $\varepsilon$ is the ratio of copper thickness $h$ to the skin depth $\delta$ in a given frequency, and $m$ is defined as a ratio in (17),

$$m = \frac{F(h)}{F(h) - F(0)}$$

where $F(0)$ and $F(h)$ are magneto motive forces (MMFs) at the limits of a layer as shown in Fig.10. The first term in (16) describes the skin effect and the second term represents the proximity effect. The proximity effect loss, in a multilayer
winding, may strongly dominate over the skin effect loss depending on the winding arrangement [40]. Interleaving transformer windings may reduce the proximity loss significantly when the primary and secondary currents are in-phase [41]. Similarly, the leakage inductance of a transformer can also be significantly reduced [42]. Fig. 10 shows the winding arrangements and MMF distributions along the vertical direction for the windings of transformer $T_1$ or $T_2$ wound on one of the outer legs. The MMF ratio $m$ for each layer is equal to 1 which results in a lower ac resistance and leakage inductance. As seen in (16), ac resistance is not only related to MMF ratio $m$, but also to the ratio $\epsilon$. A thinner copper can minimize the eddy current effect but a higher dc resistance will be compromised. Therefore, for a given frequency and winding arrangement, minimum ac resistance can be obtained by selection of proper copper thickness. Considering the cost of PCB and manufacturing simplicity, a 4-oz PCB copper thickness has been chosen for both primary and secondary windings for the experiment in this paper. In practice, PCB winding has a larger resistance compared to the calculation due to PCB vias and the fabrication tolerances.

It is noted that the validity of the expression (16) relies on negligible distances between consecutive turns, between adjacent layers, between the conductor edge and the magnetic core. Furthermore, the expression (16) is only valid for sinusoidal excitation waveform. Winding loss calculation for any current waveform to correct Dowell’s assumptions can be found in [39]. Also [43] gives generalized correction factors to be applied to Dowell’s resistance factor expression. However, these factors are usually derived from elaborated formulas and have to be determined from complicated coefficients tables.

Ferrite core has a limited saturation flux density, which requires inclusion of an airgap in the magnetic path in order to store energy for the inductors $L_1$ and $L_2$. A large airgap results in fringing flux which has two effects. First, the inductance is increased due to the effective increase in the airgap cross-sectional area, which decreases the reluctance of the gap. Second, the fringing flux induces eddy currents in the surface of nearby conductors, which causes a higher ac resistance and thereby increases the conduction loss. The fringing effect can be expressed as follows,

$$R_{ac} = F_R \cdot R_{dc}$$  \hspace{1cm} (18)

where $F_R$ represents the factor of fringing effect. Dowell’s equation (16) does not include the fringing effect caused by the airgap. Therefore $F_R$ in this case is much higher than the one calculated by Dowell’s equation. How the fringing field affects the high frequency winding loss and how to configure the windings to minimize the effect of the fringing field of the airgap have been investigated recently in [44]-[45]. The PCB windings are kept far away from the airgap in order to minimize the fringing effect in this work. The fringing effect in the PIM module has been considered by using FEA simulation tool. Fig.11 shows FEA simulation results of the fringing effect of an airgap at different windings locations. Almost 60 times of dc resistance can be obtained when the windings are close to the airgap and with 200 kHz inductor current ripple.

C. Switching Loss of MOSFets

Hard switching isolated dc-dc converters suffer increased switching loss due to leakage and stray inductances of the isolation transformer and layout, respectively. Both precise calculation and measurement of the switching losses are not straightforward due to voltage dependant parameters of the MOSFETs like the output capacitor and time scale mismatch of MOSFET drain current and voltage waveforms. MOSFETs used in boost-type isolated dc-dc converters experience inductive switching since neither the input nor the output capacitors can directly clamp their drain-to-source voltages. This condition results in switching spikes occurring on top of the drain-to-source voltage during the turn-off process [46].

During turn-off, drain-to-source capacitance voltage of the MOSFET rises with a speed determined by the current sinking capability of the gate driver circuit in order to charge the Miller capacitance. Mostly this charging is lossless when performed by an inductive element which is the case in boost type converters. However during the turn-on process the stored energy in the output capacitor of the MOSFET is dissipated. This loss may become significant in higher voltage and frequency levels.

Apart from the capacitive switching loss considerations, additional factors come into play in high input current dc/dc applications. Common source inductance (Fig.12) and gate driver voltage become the limiting factors for the MOSFET current turn off speed [47]. The negative rate of change of the drain current during turn-off induces a positive gate-to-source voltage which

may keep the MOSFET in its active region together with a high drain-to-source voltage. So this extra voltage will behave as a negative feedback in the switching seep, putting an upper limit to it. A detailed analysis on two commutation types, namely voltage limited and MOSFET limited commutations, during the turn-off of MOSFET is obtained in [46]. The boundary expression determining the commutation mode is,

\[ \frac{L_X}{L_{CS}} < \left( \frac{V_c - V_0}{2n} \right) \cdot \left( \frac{1}{2 \cdot V_{GS}(i_s)} + \frac{2n}{V_0} \right) \]

where \( L_X \) is composed of the leakage inductance and stray inductance due to the converter layout. \( L_{CS} \) is the common source inductance including the internal package inductance and the package source pin inductance. \( V_{GS}(i_s) \) is the gate voltage corresponding to the drain at the start of the turn-off process. \( V_c \) is the clamp voltage which may be provided by an external clamp circuit or the avalanche voltage of the MOSFET. Table IV shows the corresponding values of these parameters used in this paper. In order to have a practical value for \( L_{CS} \), a rule of thumb has been used. The stay and leakage inductance \( L_X \) can be found in the measurement results of Section VI. The condition in (19) can be tested for this case by inserting the parameters of Table IV which results in,

\[ \frac{L_X}{L_{CS}} < \left( \frac{V_c - V_0}{2n} \right) \cdot \left( \frac{1}{2 \cdot V_{GS}(i_s)} + \frac{2n}{V_0} \right) \]

This result confirms the commutation mode as MOSFET limited commutation as explained in [1]. Therefore, in this case the expression for the switching losses per full bridge is,

\[ P_s = f \cdot \left[ 1 + \frac{V_0}{4 \cdot n \cdot V_{GS}(i_s)} \cdot L_{CS} + L_X \right] \cdot I_{peak}^2 \]

VI. EXPERIMENTAL RESULTS

A. Results of PIM module

A 2-kW prototype has been built to verify the new integrated magnetics design approach. Input voltage is between 20-50 V
and output voltage is 400 V. Primary switches are IPA028N08N3, 80-V, 2.8-mΩ power MOSFETs from Infineon. Output rectification is handled by Silicon Carbide Schottky diodes C3D10060A with 1.5-V forward voltage drop. Magnetic parameters of the PIM module are shown in Table V. One set of EELP-64 core and an additional piece of I-64 core, all composed of N87 core material. The core material selection is directly related to the core loss. In order to feature a lower core loss, ferrite materials are usually chosen as a suitable transformer’s core material operating around hundreds kilo-hertz. Each transformer turns ratio is 1:4 ($n=4$). Air gaps with 0.5-mm length are used for the energy storage inductors $L_1$ and $L_2$. 4-oz copper thickness is used for PCB windings. Switching frequency is 100-kHz with inductor current ripple of 200-kHz. The frequency selection does not affect the integrated operation principle and the same advantages for the PIM module are achieved regardless of the frequency. And the size of converter can be further reduced if a high frequency is selected. But it is note that the frequency selection is related to the optimization design. Higher frequency may cause a higher power loss due to a high frequency eddy current effect in the windings, higher core loss in the magnetic material and higher switching loss of power MOSFETs. In addition, higher frequency causes a higher maximum output capability of the PIM module (PIM module can be operated under a high power level if a high frequency is selected).

Interleaved winding technique shown in Fig.10 is utilized to reduce the ac resistances and the leakage inductances. The measurement results for the integrated transformers and inductors are shown in Fig.13, obtained by PSM1735, impedance analyzer. The ac resistance and leakage inductance are obtained by opening secondary side and shorting both primary sides. The results in the figure have been referred to the primary side. Assuming that $T_1$ and $T_2$ have the same parameters, 52.7-nH leakage inductance and 10.3-mΩ ac resistance referred to the primary sides of each transformer can be derived. The stray parameters of the circuit are also included in the measurement results. Keeping the PCB winding far to the airgap, the fringing effect of airgap causes ac resistance of the inductors, $L_1$ and $L_2$, is 16.4 times than their dc resistances. The ac resistance of each inductor is 55.6-mΩ when the inductor current ripple works at 200-kHz. According to the above measurement results, detailed breakdown of power losses for 1.5-kW PIM module at 45-V input and 30-V input can be found in Table VI and Table VII respectively. The core loss of PIM dominates over the total power loss especially for high input voltage like 45-V. The winding loss of PIM is far less than the core loss which may not an optimization case. The solution for this is to balance the core loss and winding loss by increasing the number of turns of primary. However, it is noted that the fully interleaving may not be implemented due to the PCB layer limitation; otherwise the cost of PCB manufacture will be extremely high. The switching loss dominates over the total power loss when the converter operates at low voltage input like 30-V. As seen from (20), the

</table>
leakage inductance and stay inductance become very important in low voltage case. With the aforementioned solution of increased number of primary turns, the leakage inductance will be increased which allows a very high switching loss. Therefore, many tradeoffs exist in the PIM module and an optimization procedure needs to be done. However, this paper emphasis on the integration approach, the proof-concept demonstration rather than the optimization design.

IRS2110 high and low side gate drivers are used in the gate driver circuit together with ISO722C capacitive digital isolators for control signal protection. The control signals are produced by TMS28027 DSP. Fig.16(a) shows the experimental prototype employing the proposed PIM module. Output is filtered by several 1-uF SMD capacitors in parallel placed very close to the rectifiers for minimizing the ac loop. When the converter operates at 100-kHz, 30-V input, 400-V output and 1.5-kW output power, the current waveforms of inductors (Ch3&Ch4), the voltage (Ch2) and the current (Ch1) of transformer $T_1$ are presented in Fig.14. Observe that the two currents are identical. Removing oscilloscope offset, causes current traces to fully coincide. Also the total inductor current ripple (Ch1, AC coupled) and output current (Ch3), $V_{DS}$ (Ch2) and $V_{GS}$ (Ch4) of $S_i$ are shown in Fig.15 respectively.

High stability (< 10 ppm) 0.1 % shunt resistors are used for high precision of the efficiency measurements. Agilent 34410A high precision multimeters are used for all measurements. Current sense signals are shielded and fitted with common mode filters. Efficiency curves of the converter employing the PIM module when the output voltage is 400-V are shown in Fig.17. Maximum efficiency of 95.9% has been observed with 45-V input voltage, 400-V output voltage and 1.8-kW output power. And the same maximum efficiency can be observed at 30-V input voltage, 400-V output voltage and 1-kW. In low output power, the efficiency of 30-V input is much higher than that of 45-V input this is due to the fact that the low number of primary turns in this case causes the core loss of PIM dominating over the total power loss which has been mentioned in the previous. With increased output power, the switching loss becomes a crucial part in total power loss. Therefore, a lower efficiency at 30-V input can be observed. Fig. 18 shows a thermal photo of PIM module at 45-V and 1.5-kW in which is the worst case for the core loss. Notice that a forced air flow from fan is used for cooling down the converter. As shown in the photo, the heat mostly concentrates on the side legs rather than the center leg. This is coincident with the analysis of core loss in section V.

**B. Comparison**

In order to demonstrate the advantages of PIM such as low profile and high efficiency, a comparison between the PIM and three different separated cases has been done. In order to make a fair comparison, all switching devices, gate drivers, and capacitors are kept the same. The prototype of separated case-1 is shown in Fig.16(b) which is consisted of single inductor with integrated balancing transformers and two discrete transformers. The detailed principle about this structure can be found in [26]. In separated case-1, two turns single inductor are wound in EIIP-58 core with 0.5-mm airgap length and two turns of integrated balancing transformer are wound in each side leg. The
two discrete transformers are both employing EILP-43 cores with two turns in primary sides and 8 turns in secondary sides. N87 core material is used for all cores in the separated case-1. And full interleaved winding arrangement is also used in this case. The separated case-2 is partially using integrated technology shown in Fig.19. The PCB winding and core size are kept the same with PIM module. Two E-I cores have been separated by adding a single I-core on the basis of PIM module. A single inductor and a single transformer are still integrated into the E-I core. A complete separation has been implemented in the separated case-3, consisting of four discrete magnetic components, L₁, L₂, T₁, and T₂. And the windings of transformer still keep the same arrangements with PIM module shown in Fig.19. The two inductors and two transformers are using the same core geometry EILP-64. Obviously, the PIM module has the smallest footprint and fewest numbers of components compared to the other separated cases. Fig.20 and Fig.21 show the efficiency comparisons among the four cases at 45-V input and 30-V input respectively. Regarding to the power losses of the separate case-2 and case-3, the only difference with PIM case is to have higher core loss. This is because the flux is cancelled in the shared I-core in PIM case, causing a lower core loss. Winding layouts are not changed and thus the other power losses are kept the same with PIM case. From the efficiency curves, the case-2 and case-3 almost have the same core loss at 45-V input and the PIM has 1% improvement at 1.5-kW output power. When the input voltage is 30-V, the efficiency of the separated case-3 is slightly higher than that of the case-2. The PIM case has almost 0.5% improvement at 1.5-kW output power. Regarding to the separated case-1, some design parameters including the number of turns of integrated balancing transformers, the winding widths, the winding lengths, the winding arrangements and the core geometries are different with the PIM case. Therefore, the difference in power loss between the PIM case and the case-1 is not only the core loss, but also the winding loss and the switching loss. The power loss breakdown for separated case-1 is shown in Table VIII. From the efficiency figures, the separated case-1 has lower efficiencies than the PIM case at nominal output power. Notice that the comparison between the PIM case and separated case-1 is not fair since the two cases are both not optimized. And the efficiency of separated case-1 might be improved by changing winding widths and winding arrangements and enhancing the value of inductor. Larger core geometries could also be used for the efficiency improvement. However, the power density (larger core geometries) and the cost (more PCB layers for higher inductance) will be lost if the aforementioned methods are used.

VII. Conclusion

This work presents a new integrated magnetics approach to combine all magnetic components of the primary-parallel isolated boost converter into an E-I-E core structure. Since the design approach allows the transformers and inductors are electromagnetically uncoupled, it can be extended into many other isolated dc-dc topologies where multiple transformers and multiple inductors are involved in. The similar matter results are achieved for the extended topologies and all the advantages aforementioned will not be losing. The design approach provides a low footprint, low cost and high efficiency. Also, the integrated magnetics with planar components are made from pre-formed assemblies, thus the assembly process itself has only a few stages. This simplification of assembly allows the PIM to be manufactured with very high repeatability and with increased accuracy. The drawback of the PIM module is to limit the maximum the output power capability due to the overlapped flux. The detailed limitation of power capability has been presented and analyzed. Power loss analysis of the converter has been investigated in-depth. Test results from a 2-kW experimental prototype verify that converter employing the PIM module is fully functional and electromagnetically equivalent. An
efficiency of 95.9% can be achieved during 1.5-kW nominal operating conditions. Experimental comparisons between the PIM module and three separated cases have illustrated the PIM operating conditions. Experimental comparisons between the negligible, (28) ~ (30) can be obtained, windings. With assumption that leakage flux through the air is

\[ L_{11} = \frac{N_1^2}{2 \cdot R_1 + R_2} \]

\[ L_{22} = \frac{N_2^2}{2 \cdot R_1 + R_2} \]

Combining (21) and (22), the following equations are obtained,

\[ \phi_1 = \frac{2 \cdot N_1 \cdot (R_1 + R_2)}{\Delta} \cdot i_{m1} + \frac{N_2 \cdot R_2}{\Delta} \cdot i_{m2} \]

\[ \phi_2 = \frac{N_1 \cdot R_2}{\Delta} \cdot i_{m1} + \frac{2 \cdot N_2 \cdot (R_1 + R_2)}{\Delta} \cdot i_{m2} \]

where

\[ \Delta = 4 \cdot R_1^2 + 8 \cdot R_1 \cdot R_2 + 3 \cdot R_2^2 \]

Taking the partial derivative in (23) and (24),

\[ \frac{d\phi_1}{dt} = \frac{2 \cdot N_1^2 \cdot (R_1 + R_2)}{\Delta} \cdot \frac{di_{m1}}{dt} + \frac{N_1 \cdot N_2 \cdot R_2}{\Delta} \cdot \frac{di_{m2}}{dt} \]

\[ \frac{d\phi_2}{dt} = \frac{N_1 \cdot N_2 \cdot R_2}{\Delta} \cdot \frac{di_{m1}}{dt} + \frac{2 \cdot N_2^2 \cdot (R_1 + R_2)}{\Delta} \cdot \frac{di_{m2}}{dt} \]

(27) is rewritten from (25) and (26),

\[ \begin{bmatrix} \lambda_1 \\ \lambda_2 \end{bmatrix} = \begin{bmatrix} 2 \cdot N_1^2 \cdot (R_1 + R_2) & N_1 \cdot N_2 \cdot R_2 \\ N_1 \cdot N_2 \cdot R_2 & 2 \cdot N_2^2 \cdot (R_1 + R_2) \end{bmatrix} \begin{bmatrix} i_{m1} \\ i_{m2} \end{bmatrix} \]

where the flux linkages \( \lambda_1 \) and \( \lambda_2 \) are the time integrals of the transformer primary voltages, \( i_{m1} \) and \( i_{m2} \) are the individual excitation currents, \( L_{11} \) and \( L_{22} \) are their self-inductances, \( L_M \) represents mutual inductance between the two transformer windings. With assumption that leakage flux through the air is negligible, (28) ~ (30) can be obtained,

\[ k = \frac{L_M}{L_{11}} = \frac{2 \cdot (R_1 + R_2)}{R_2} \]

The results of magnetizing inductance of transformers are the same with that in Section III. \( k \) represents the coupling coefficient between \( T_1 \) and \( T_2 \). According to the geometry of core, \( k=0.4 \) can be obtained for their coupling coefficient.
