Abstract—Dielectric Elastomer (DE) transducers have emerged as a very interesting alternative to the traditional electrodynamic transducer. Lightweight, small size and high maneuverability are some of the key features of the DE transducer. An amplifier for the DE transducer suitable for audio applications is proposed and analyzed. The amplifier addresses the issue of a high impedance load, ensuring a linear response over the midrange region of the audio bandwidth (100 Hz – 3.5 kHz). THD+N below 0.1% are reported for the ±300 V prototype amplifier producing a maximum of 125 V ar at a peak efficiency of 95%.

INTRODUCTION

Class D audio amplifiers are commonly used in sound reproduction driving electrodynamic transducers [1], [2], [3], [4], [5], [6], [7]. While these audio systems are dominating the market of sound reproduction, they suffer from the poor efficiency imposed by the electrodynamic transducer, and the weight of the electromagnet. As a consequence the audio community is constantly searching for new audio transducers. An alternative to the electrodynamic transducer is the electrostatic transducer. Electrostatic transducers are known from their usage in electrostatic loudspeakers, however Dielectric Elastomers (DE) can also be used to form an electrostatic transducer [8], [9], [10]. Such capacitive transducers present a high impedance, frequency depended nonlinear load to the amplifier. A DE transducer is shown in figure 1. The DE transducer is constructed by printing compliant electrodes on a thin piece of silicone. Commercial electrostatic loudspeakers are driven from tube, linear or audio-transformer based amplifier solutions. Consequently these systems suffer from being bulky, fragile and inefficient. In order to establish the full potential of the DE transducer, a new generation of audio amplifiers must be developed. These amplifiers should have a high power density, low power loss and be robust. Accordingly it is proposed to use a switch-mode audio amplifier or class D amplifier for driving the DE transducer [11], [12]. Class D audio amplifiers are known for their low power consumption, high power density and excellent audio figures (for instance low Total Harmonic Distortion plus Noise or THD+N) [4], [13], [1], [2]. In this paper a half-bridge based class D amplifier is proposed as amplifier for the DE transducer. A hysteretic based self-oscillating bandpass current mode control scheme is suggested, ensuring high loop gain and thus excellent THD+N. It should be noted, that DE transducers and their amplifiers are not limited to the application of sound reproduction. Micro-robotics with DE transducers is another application, which has received interest in recent years [14].

THEORY

When driving a DE transducer it is appropriate to give a formal definition of the term efficiency. The first order approximation will yield a capacitive load. Accordingly no real power will be delivered to the load. Efficiency will thus be defined as

$$\eta = \frac{P_{\text{Out}}}{P_{\text{Out}} + P_{\text{In}}}$$

(1)

where $P_{\text{Out}} = \frac{V_{\text{rms}}^2}{\pi f_{\text{Ref}} R_{\text{loop}}}$, the reactive power delivered to the load, and $P_{\text{In}}$ corresponding to the real power consumed by the amplifier. This definition of the term efficiency will be used throughout the paper.

Losses

The paper analysis the power stage of figure 2. Notice, that the inductor current equals the current of $C_{\text{DE}} (i_L(t) = i_{\text{CDE}}(t))$, because the parallel resistance of $C_{\text{DE}}$, $R_p$, has a value of 1 MΩ or above [10]. The current $i_L(t)$ is a superposition of the ripple ($\Delta i_L(D)$) and the sinusoidal reference or audio current ($i_{\text{Ref}}(t)$)

$$i_L(t) = \Delta i_L(D) + i_{\text{Ref}}(t)$$

(2)

The following definitions will be used...
Semiconductor loss

The semiconductor losses are divided into conduction and switching losses. The conduction loss caused by the MOSFET on resistance, \( R_{DS,on} \), is

\[
P_{DS(on)} = R_{DS(on)} I_{L,\text{rms}}
\]

(10)

The switching loss can be approximated by [16]

\[
P_{SW} = \left\{ \begin{array}{ll}
4f_{SW}C_{DS}V_{CC}^2 & i_{Ref}(M) \leq \Delta I_l(M) \\
\frac{f_{SW}V_{CC}}{2} \tau i_{Ref} & i_{Ref}(M) > \Delta I_l(M)
\end{array} \right.
\]

(11)

with

\[
\tau(I_l) = \frac{R_Q G_{QD}}{\sqrt{\frac{1}{V_{GS,th}^2} + \frac{1}{V_G - V_{GS,th} - \frac{V_G}{I_S}}}} + R_C I_{SS} \ln \left( \frac{V_{GS,th} + \frac{V_G}{I_S}}{V_{GS,th} - \frac{V_G}{I_S}} \right)
\]

(12)

Zero voltage switching

Switching losses can be limited by ensuring soft switching or zero voltage switching (ZVS) of the MOSFETs. The quasi-square wave ZVS buck converter is analyzed in [17], and ZVS is guaranteed at 50% duty cycle, if the switches are operated with sufficient deadtime. The deadtime can be evaluated as

\[
t_{\text{Dead}} = \frac{\pi}{2} \sqrt{L C_{SW}}.
\]

(14)

The resonance tank of \( L \) and \( C_{SW} \) reaches its maximum amplitude at \( \frac{\pi}{T} \). \( T \) being the resonance period. \( C_{SW} \) equals to two times the mosfet drain-source capacitance plus any other capacitive couplings at the switching node. The later includes coupling to the heatsink, the equivalent capacitance constructed from the output filter inductor parallel capacitance and \( C_{DEAP} \) etc.

Dead-time distortion

Several publications have analyzed the influence of pulse-time errors on THD [18], [19], [16]. These are traditional divided into the categories of dead-time distortion, finite switching speed and conduction state errors. When operating the power stage at ZVS, the dead-time distortion becomes a key concern. It is shown in [16], that dead-time distortion is a function of the ratio between reference and ripple current. This section analyzes dead-time distortion for a class D amplifier driving a capacitive load. Voltage mode control is assumed, meaning that the output current no longer can be considered constant with respect to frequency. This is unlike the case of driving an electrodynamic loudspeaker, where the load typically is assumed being resistive, and those the output current does not change with frequency. Let the THD arising from dead-time distortion being defined as [16]

\[
THD_d(M, \alpha_d, \alpha_t) = \frac{\Delta(\alpha_t)}{M - \alpha_d \Delta(\alpha_d)}
\]

(15)

\[\Delta(\alpha_t) = \sqrt{\sum_{i=2}^{N_{ harmonics}} \left( \frac{2a_d \sin \left( \frac{\pi i t}{T} \right)}{i^2} \right)^2}
\]

(16)
where the dead-time delay factor is the ratio of the dead-time to the period of the switching frequency

$$\alpha_d = \frac{t_d}{T_{sw}} \tag{15}$$

and the ripple current factor

$$\alpha_I = \frac{\Delta i_L(M)}{i_{ref}(M)} \tag{16}$$

The ripple current factor is the amplitude of the ripple current divided by the reference current. Both being functions of the modulation index, M.

Using the ripple current factor $\Delta(\alpha_I)$ of equation (15) is defined

$$\Delta(\alpha_I) = \begin{cases} 
0 & i_{ref}(M) \leq \Delta i_L(M) \\
\frac{\pi}{2} - \arcsin(\alpha_I) & i_{ref}(M) > \Delta i_L(M) 
\end{cases} \tag{17}$$

### ANALYSIS

The following analysis assumes the basic design parameters of Table I. Using these parameters $\Delta i_L = 1.07 \text{ A}$. With a maximum output current of $300 \text{V} \times 3.5 \text{kHz} 	imes 100 \text{nF} = 660 \text{mA}$, the dead-time distortion does not compromise the overall THD even though the power stage is operated at ZVS.

### IMPLEMENTATION

It is proposed to use a half-bridge power stage with hysteresis bandpass current mode control (BPCM), as amplifier for the DE transducer. BPCM control schemes for class D audio amplifiers driving electrodynamic transducers are well-known [6], [4], [20], [5], [21]. The big advantage of such control schemes is the fact, that stability is maintained, even when no resistive load is connected to the amplifier. As a consequence the zobel network used to damp the high Q of an unloaded amplifier can be eliminated [6]. Implementation of the BPCM scheme is achieved by either direct measurement or estimation of the inductor current [22], [8]. For this application the inductor current is measured using a current sense transformer. Accordingly an isolated feedback signal with enough bandwidth to handle the switching frequency is obtained. Figure 4(a) shows a schematic of the Class D amplifier with BPCM control scheme, while figure 4(b) gives the small-signal model of the amplifier.

#### A. Self-oscillation

Oscillation is ensured by shaping the open-loop frequency response to have a phase shift of $360^\circ$ and unity gain at the targeted switching frequency. This is the Barkhausen Oscillation criterion. It can be shown, that the switching frequency is described by the function [7], [6]

$$f_{sw}(D) = \frac{D(1-D)}{2V_{Hyst}^2 + t_D} \tag{18}$$

With $K$ defined as:

$$K = 2V_{CC} \times \text{step}\{\lim_{s \rightarrow \infty} G_{Ctrl}(s)\} \tag{19}$$

For the purpose of designing the self-oscilation control loop, the controller transfer function must be defined

$$G_{Ctrl}(s) = \frac{v_{Carrier}(s)}{v_{PWM}(s)} \tag{20}$$

$$= \frac{G_{ref}(s)}{G_{Ctrl}(s) \times G_{sense}(s) \times \frac{1}{v_{Hyst}^2 + t_D}} \tag{21}$$

$K$ can be derived using equation (19) and (21)

$$K = 2V_S K_{Ctrl} N R_{Sense} \tag{22}$$

EXPERIMENTAL RESULTS

A prototype amplifier has been constructed. The amplifier operates from ±300 V delivering a maximum power of 125 Var to a 100 nF capacitive load. Figure 5 shows the prototype amplifier, which is based on a Si8235 digital isolated gate driver. The BPCM control scheme are implemented using a single-supply control circuitry with a THS4221 comparator and LVM7219 operation amplifiers. Current measurement is performed using the current sense transformer, CST1-070LB, of Coilcraft. A polypropylene capacitor is used as dummy load to perform all measurements. Table III shows the key component values of the prototype amplifier.

Note, that the efficiency at 100 Hz is below 42 %. Because the output voltage is kept fixed with respect to frequency, the reactive output power will drop inversely proportional with frequency. At 100 Hz the switching loss becomes comparable with the reactive output power. An efficiency above 90 % is achieved for the reference frequency 3.5 kHz. Voltage mode control of electrostatic transducers is preferred for applications were displacement is of concern. Charge mode control ensures greater linearity at the expense of displacement [23].

Fig. 5: Power stage used for the prototype amplifier.

THD+N and closed-loop response

THD+N is measured using an APX525 audio analyzer and a voltage attenuation interface. The voltage attenuation interface is necessary in order to protect the input-stage of the audio analyzer. Design and implementation of the voltage attenuation
interface is well-described in the literature [11], [24]. Figure 7(a) gives the measured THD+N as function of the reference voltage for the frequencies of 100 Hz and 1 kHz. THD+N is below 0.1% over a significant part of the operation range. Noise is the dominating factor in the measured THD+N. The measured small-signal closed-loop frequency response is given in Figure 7(b). The response is flat (within 3 dB) over the midrange region of 100 Hz – 3.5 kHz.

CONCLUSION

A class D audio amplifier for dielectric elastomer transducers is proposed and analyzed. The amplifier addresses the issue of a high impedance load, ensuring a linear response over the midrange region of the audio bandwidth (100 Hz – 3.5 kHz), potentially paving the way for increased industry adoption of the highly promising technology of dielectric elastomers. THD+N below 0.1% are reported for the ±300 V prototype amplifier producing a maximum of 125 Var at a peak efficiency of 94%.
