We study theoretically Coulomb drag in capacitively coupled quantum dots (CQDs)—a bias-driven dot coupled to an unbiased dot where transport is due to Coulomb mediated energy transfer drag. To this end, we introduce a master-equation approach that accounts for higher-order tunneling (cotunneling) processes as well as energy-dependent lead couplings, and identify a mesoscopic Coulomb drag mechanism driven by nonlocal multielectron cotunneling processes. Our theory establishes the conditions for a nonzero drag as well as the direction of the drag current in terms of microscopic system parameters. Interestingly, the direction of the drag current is not determined by the drive current, but by an interplay between the energy-dependent lead couplings. Studying the drag mechanism in a graphene-based CQD heterostructure, we show that the predictions of our theory are consistent with recent experiments on Coulomb drag in CQD systems.

DOI: 10.1103/PhysRevLett.116.196801

Electronic systems brought into close proximity may exhibit Coulomb drag [1,2]: a current in one system induces a current (or a voltage) in a nearby undriven system. Importantly, the effect arises solely due to Coulomb interactions between the charge carriers in the two systems. Coulomb drag has been studied extensively in bulk two-dimensional systems, both experimentally [3–5] and theoretically [6–9], and has recently experienced a revival in one-dimensional systems [10–14] and graphene heterostructures [15–20].

In mesoscopic systems with broken translational invariance, e.g., quantum point contacts or quantum dots (QDs), momentum is not a good quantum number as in extended systems. Instead of momentum transfer, it is more natural to view mesoscopic Coulomb drag [21–25] as an interaction mediated energy transfer between the drive and the drag system. Such energy-transfer drag plays a central role in, for example, quantum measurements where a detector and a system exchange energy in a measurement on the system [26]. In this case, the drag can either constitute the signal in the detector generated by the measured quantum noise in the system [27–29], or be a disturbance in the system due to the measurement [30,31], i.e., detector backaction.

In addition to energy transfer, Coulomb drag in capacitively coupled QDs (CQDs) relies on an asymmetry in the drag system [25]. This has been demonstrated in coupled double quantum dots [32], and recently in coupled single QDs [33,34], where the asymmetry originates from the couplings to the leads. In the latter, Coulomb-drag effects beyond conventional mesoscopic QD drag [25] were reported [33]. Not only are such effects of fundamental scientific interest, but they may also be important for the performance of thermoelectric CQD devices [35–38].

In this work we introduce a theoretical framework for the description of Coulomb drag in CQDs taking into account higher-order tunneling (cotunneling) processes, and thereby going beyond conventional QD drag [25]. We uncover a drag mechanism driven by nonlocal correlated multielectron cotunneling processes where energy transfer is mediated by bias-induced switching of the CQD states. At the triple points of the CQD charge stability diagram [39] sketched in Fig. 1(a), it resembles a stochastic ratchet
mechanism which, like charge pumping mechanisms [40], results in drag via excursions [in state space; see Fig. 1(b)] around the triple points. Our theory pinpoints the conditions for drag in terms of microscopic quantities and shows that the direction of the drag current is independent on the drive current and exhibits a nontrivial dependence on the lead couplings in the drag system.

We demonstrate the rich properties of the drag mechanism by studying drag in the graphene-based QD structure illustrated in Fig. 1(c). Such experimentally realizable graphene-based QD structures are unique due to their large tunability [41–45], large interdot charging energies [33], and built-in graphene leads. We envision structures in which local gating allows us to control the chemical potentials of the lead regions [46,47] and create, e.g., \( p \)-QD-\( n \) junctions across the individual QDs. As we demonstrate below, this opens the opportunity to control the direction of the drag current. Finally, we elaborate on the role of the drag mechanism in the recently observed Coulomb drag in graphene-based QD heterostructure [33].

**General model and theory.**—We consider a generic (spinless) model for two capacitively coupled QDs—a biased drive \( (i = 1) \) and an unbiased drive \( (i = 2) \) QD—with one level each, \( H_{\text{QD}} = \sum_{\alpha} \epsilon_{\alpha} n_{\alpha} + U_{\text{12}} n_{1} n_{2} \), where the dot levels are controlled by gate voltages \( \epsilon_{\alpha} = -eV_{\alpha} \), \( n_{\alpha} = d_{\alpha}^{\dagger}d_{\alpha} \) is the dot occupation, and \( U_{\text{12}} = e^{2}/2C \) is the capacitive interdot Coulomb interaction. The dots are coupled to separate sets of source and drain contacts, \( H_{a} = \sum_{\alpha} \xi_{\alpha} c_{\alpha}^{\dagger} c_{\alpha} \), with \( \xi_{\alpha} = \epsilon_{\alpha} - \mu_{\alpha} \) \((\alpha = L_{i}, R_{i}) \). Here, \( \mu_{L_{i}}/\mu_{R_{i}} = \pm eV_{\text{sd}}/2 + \mu_{0} \) and \( \mu_{L_{i}}/\mu_{R_{i}} = \mu_{0} \). via tunnel Hamiltonians \( H_{T} = \sum_{\alpha} t_{\alpha} c_{\alpha}^{\dagger} d_{i} \). In contrast to the usual wide-band approximation where the lead couplings are assumed constant, we here consider energy-dependent couplings \( \Gamma_{\alpha}(\epsilon) = 2\pi\rho_{\alpha}(\epsilon)|t_{\alpha}(\epsilon)|^{2} \), where \( \rho_{\alpha} \) is the density of states (DOS) in lead \( \alpha \) and \( t_{\alpha} \) is the tunnel coupling. Like in conventional QD drag [25,33], this is the key ingredient for the drag mechanism described below.

We describe the transport through the drive and drag dots with a master equation approach valid for \( k_{B}T \gtrsim \Gamma_{\alpha}^{-1} \) [48]. The occupation probabilities \( p_{m} \) for the QD states, \( |m\rangle = |n_{1}n_{2}\rangle \in \{00, 10, 01, 11\} \), are determined by the rate equations

\[
\dot{p}_{m} = -p_{m} \sum_{n \neq m} \Gamma_{mn} + \sum_{n \neq m} p_{n} \Gamma_{nm},
\]

which together with the normalization condition \( \sum_{m} p_{m} = 1 \) are solved for the steady-state probabilities, i.e., \( \dot{p}_{m} = 0 \).

The rates for tunneling-induced transition between the states are obtained from the generalized Fermi golden rule [48],

\[
\Gamma_{mn} = \frac{2\pi}{\hbar} \sum_{f'} W_{f'} |\langle f'|T|i\rangle|^{2} \delta(E_{f} - E_{i}).
\]

Here, \(|i/f\rangle = |m/n\rangle \otimes |\bar{i}/f\rangle\) are products of QD and lead states, the sum is over possible initial \(|\bar{i}\rangle\) and final \(|f\rangle\) states of the leads, \( W_{f'} \) is the probability for the initial lead state \(|\bar{i}\rangle\), and \( T = H_{T} + H_{\text{QD}}G_{0}H_{T} + \ldots \) is the \( T \) matrix with \( G_{0} = 1/(E_{f} - H_{0}) \) denoting the Green function in the absence of tunneling, i.e., \( H_{0} = H_{\text{QD}} + \sum_{a} H_{a} \). The correlations between the occupations of the QDs are fully accounted for in \( G_{0} \), which is treated exactly.

To lowest order in the tunneling Hamiltonian, the transitions between the states are given by sequential tunneling processes with rates

\[
\Gamma_{m,11}^{\alpha} = h^{-1} \Gamma_{\alpha}(\Delta_{m11}) f_{\alpha}(\Delta_{m11}),
\]

\[
\Gamma_{m,00}^{\alpha} = h^{-1} \Gamma_{\alpha}(\Delta_{00,m})[1 - f_{\alpha}(\Delta_{00,m})],
\]

\[
\Gamma_{00,n}^{\alpha} = h^{-1} \Gamma_{\alpha}(\Delta_{00,n}) f_{\alpha}(\Delta_{00,n}),
\]

\[
\Gamma_{11,n}^{\alpha} = h^{-1} \Gamma_{\alpha}(\Delta_{n11})[1 - f_{\alpha}(\Delta_{n11})],
\]

where \( m, n \in \{10, 01\} \), \( f_{\alpha} \) is the Fermi function in lead \( \alpha \), and \( \Delta_{mn} = E_{n} - E_{m} \).

The next-to-leading order term in the \( T \) matrix gives rise to elastic and inelastic cotunneling through the individual QDs [49–51]. In addition, we identify a nonlocal cotunneling process mediated by the capacitive interdot coupling. This is a correlated two-electron tunneling event in which the QD switches between the 10→01 states in one coherent process. The rate for nonlocal cotunneling processes which transfer an electron from lead \( \alpha \) to lead \( \beta \) is given by

\[
\Gamma_{mn}^{\alpha\beta} = \frac{\pi}{2\hbar} \frac{d\epsilon}{f_{\alpha}(\Delta_{mn})f_{\beta}(\Delta_{mn})[1 - f_{\beta}(\epsilon)]}
\times \left| \frac{1}{\epsilon + \Delta_{11,n} - \epsilon} - \frac{1}{\epsilon + \Delta_{m00}} \right|^{2},
\]

where \( m, n \in \{10, 01\} \) and the terms in the last line account for the energy of the virtually occupied intermediate 00/11 states. To evaluate the cotunneling rates at finite temperature and bias, we have generalized the commonly applied regularization scheme [52,53] to the situation with energy-dependent lead couplings [54].

From the solution to the master equation (1), the currents in the various leads are obtained as

\[
I_{\alpha} = -e \sum_{mn} p_{m} (\Gamma_{mn}^{\alpha} - \Gamma_{mn}^{\alpha*}),
\]

where \( \Gamma_{mn}^{\alpha} \) \((\Gamma_{mn}^{\alpha*})\) denotes the rate for processes that transfer an electron into (out of) lead \( \alpha \), and the drive and drag currents are defined as \( I_{\text{drive}} = I_{L_{1}} = -I_{R_{1}} \) and \( I_{\text{drag}} = I_{L_{2}} = I_{R_{2}} \), respectively.

**Drag mechanism.**—In the following, we focus on the regime of low bias on the drive QD, \( eV_{\text{sd}} \ll U_{12} \), where the
conventional drag mechanism [25] is suppressed. Fixing the gate voltages to, e.g., the point below the 10,11 degeneracy line at the upper triple point in Fig. 1(a), a finite bias on the drive QD opens for the sequence of transitions illustrated in Fig. 1(b),

$$|10\rangle \xrightarrow{\text{seq}} |01\rangle \xrightarrow{\text{seq}} |11\rangle \xrightarrow{\text{seq}} |10\rangle.$$  \hspace{1cm} (9)

For $$eV_{sd} > |\Delta_{10,01}|, |\Delta_{01,11}| \gg k_BT,$$ the two first transitions are open in both directions, whereas the third transition is only open in the forward direction because the drag QD is unbiased. In addition to a drive current, this may induce a drag current via steps where the drag QD is repeatedly filled and emptied. This is possible via the first step alone (cotunneling-only), or through the full sequence (cotunneling-assisted drag). The two mechanisms govern the drag, respectively, away from and at the triple points [cf. Fig. 1(a)]. Note that the nonlocal cotunneling process is instrumental in both cases.

In order to generate a drag current, the drag QD must be filled and emptied at preferentially separate leads. This requires an asymmetry in the drag system. To identify the exact conditions, we expand the lead couplings around the equilibrium chemical potentials $$\mu_0, \Gamma_0(e) \approx \Gamma_0 + \xi \partial \Gamma_0 / \partial \mu_0$$, where $$\xi = e - \mu_0, \Gamma_0 = \Gamma_0(\mu_0),$$ and $$\partial \Gamma_0 / \partial \mu_0 |_{\mu_0}.$$ Along the 10,01 degeneracy line where $$\Delta_{10,01} = 0,$$ and in the nonlinear regime $$eV_{sd} \gg k_BT$$ (but still $$eV_{sd} < U_{12}$$) where the transport in the drive QD is unidirectional, we find for the drag current,

$$I_{\text{drag}} \propto \Gamma_{L,0} \Gamma_{R,0} \left( \Gamma_{L,0} \partial \Gamma_{R,0} - \Gamma_{R,0} \partial \Gamma_{L,0} \right) F(V_{sd}).$$ \hspace{1cm} (10)

where $$F(V_{sd}) = V_{sd}^2 \log V_{sd}$$ for cotunneling-only and cotunneling-assisted drag, respectively. The factor in parentheses in the numerator gives the conditions for drag. Notably, the drag is zero if the lead couplings to the drag QD are constant or differ by a multiplicative factor. Furthermore, the direction of the drag current is determined by two factors concerning the lead couplings to the drag QD: (i) their asymmetry, and (ii) their derivatives.

**Drag in graphene-based CQDs.**—We now proceed to study the drag effect in an idealized version of the graphene-based CQD structure illustrated in Fig 1(c). The QDs are assumed to be connected to bulk graphene leads with linear DOS, $$\rho_\alpha(e) = \left( g_\alpha g_\rho / 2\pi (h\nu)^2 \right) |e - E_\alpha|,$$ which govern the energy dependence of the lead couplings, i.e., $$\Gamma_\alpha(e) = 2\pi \rho_\alpha(e) |t_\alpha|^2,$$ where $$t_\alpha$$ is constant, and where the positions of the Dirac points, $$E_\alpha = -eV_\alpha,$$ are controlled by local gates [see Fig. 3(a)]. This allows us to tune both the strength of the lead couplings, $$\Gamma_\alpha \propto |\mu_0 - E_\alpha|,$$ as well as their derivatives, $$\partial \Gamma_\alpha / \partial \mu_0 \approx 0$$ on the upper or lower Dirac cones. In order to meet the conditions for a nonzero drag current, $$E_{L,2} \not\equiv E_{R,0}$$ like in Fig. 3(a) is necessary. Asymmetric tunnel couplings alone, $$t_{L,2} \neq t_{R,0} \to \Gamma_{L,2}(e) \propto \Gamma_{R,0}(e),$$ is not enough.

In Figs. 2(a) and 2(c) we show the numerically calculated currents through the drive and drag QDs as a function of gate voltages for the situation in Fig. 3(a) and $$k_BT \ll eV_{sd} < U_{12}.$$ The current through the drive QD in Fig. 2(a) is nonzero along the 00,10 and 01,11 degeneracy lines, and the 10,01 degeneracy line where it is dominated by, respectively, sequential tunneling and nonlocal cotunneling. In addition, elastic cotunneling through the drive QD appears as a background in the Coulomb-blockaded regions.

The induced drag current is shown in Fig. 2(c). A finite drag current is observed along the 10,01 degeneracy line where the nonlocal cotunneling channel is open. With the bias applied symmetrically to the drive dot, this is the case for $$eV_2 - V_1 = |\Delta_{10,01}| < eV_{sd}/2.$$. Away from the triple points, $$|\Delta_{10,00,11}/11| \gg eV_{sd},$$ the drag is driven by nonlocal cotunneling only. In the vicinity of the upper (lower) triple point, $$|\Delta_{01,11} \gg eV_{sd} (|\Delta_{10,00}| \ll eV_{sd}),$$ the bias on the drive QD opens the 01→11 (10→00) transition via sequential tunneling, and the drag changes to cotunneling-assisted drag. This results in an enhanced drag current compared to the cotunneling-only drag.

Figures 2(b) and 2(d) show the bias dependence of the drive and drag currents at the gate voltages marked by dots in Figs. 2(a) and 2(c). In the linear low-bias regime, $$eV_{sd} < k_BT, I_{\text{drive}} \propto V_{sd}$$ and $$I_{\text{drag}} \propto V_{sd}^2$$ for $$|\Delta_{10,01}| < k_BT$$ (red, yellow, and green dots). The drag current is
linear in \( V_{sd} \) only at bias voltages \( eV_{sd} \ll k_B T \) (not shown). For \( |\Delta_{10,01}| > k_B T \) (blue dot), nonlocal cotunneling is exponentially suppressed, \( \Gamma_{10,01} \sim e^{-\Delta_{10,01}/k_B T} \), resulting in a vanishing drag current. The drive current, however, remains finite due to elastic cotunneling. In the nonlinear regime, \( eV_{sd} > k_B T \), \( I_{drag} \sim V_{sd}^2 \) up to \( eV_{sd} \sim \max(2|\Delta_{10,01}| / |\Delta_{10,01,11}|) \) where it experiences a crossover to a \( I_{drag} \sim \log V_{sd} \) dependence in agreement with Eq. (10). At even higher bias, \( eV_{sd} \gtrsim U_{12} \), the conventional drag mechanism [25], which is driven by sequential tunneling, takes over (see also below).

From Eq. (10) it is clear that the direction of the drag current depends, in a nontrivial way, on the lead couplings in the drag system. This is demonstrated in Fig. 3, which shows the drag current at the upper triple point as a function\( \Delta_{10,01} \) in the stability diagram. At the diagonal we have \( \Gamma_{L_2} = \Gamma_{R_2} \), and hence the drag vanishes. Off the diagonal, \( \Gamma_{L_2} \neq \Gamma_{R_2} \), and \( \partial \Gamma_{L_2} = \partial \Gamma_{R_2} \), the factor \( \Gamma_{L_2} - \Gamma_{R_2} \) governs the sign of the drag current. Upon crossing the Dirac point in one of the leads, the drag changes sign due to an inversion in the sign of the corresponding DOS derivative. Remarkably, the drag becomes independent on \( |\mu_0 - E_{L_0,R_0}| \) in this case. This follows from the fact that for symmetric tunnel coupling \( \partial \Gamma_{L_2} = -\partial \Gamma_{R_2} \), which leads to a cancellation of the \( \Gamma_{L_2} + \Gamma_{R_2} \) factors in Eq. (10). For asymmetric tunnel coupling this is not the case. The unconventional sign of the mesoscopic drag, which we have verified also holds for the conventional drag mechanism [25], is in stark contrast to that of the drag in coupled graphene layers [19].

In the bias spectroscopy of the CQDs shown in Fig. 4, distinct fingerprints of nonlocal cotunneling and the drag mechanism can be observed inside the so-called Coulomb-blockade diamonds, where the sequential tunneling drive and drag currents are suppressed. It shows the drive (top) and drag (bottom) currents at the center of the stability diagram (green dot in Fig. 2) as a function of gate detuning and drive bias. In the low-bias Coulomb-blockaded regime, \( e|V_{sd}| < \min(U_{12} + |V_2 - V_1|, 2U_{12}) \), nonlocal cotunneling manifests itself in nonzero drive and drag currents in the region \( |V_{sd}|/2 > |V_2 - V_1| \), which at \( \Delta_{10,01} = 0 \) extends down to zero bias. At high bias, \( \frac{e|V_{sd}|}{U_{12}} > e|V_2 - V_1| \), sequential tunneling dominates both the drive and drag currents. However, for \( e|V_2 - V_1| > U_{12} \), where the conventional drag mechanism [25] is suppressed, cotunneling-assisted drag extends the region with nonzero drag to \( e|V_2 - V_1| < e|V_{sd}|/2 \). The different slopes \( s \) of the boundaries to the regions where, respectively, sequential tunneling (dotted, \( |s| = 1 \)) and nonlocal cotunneling (dashed, \( |s| = 2 \)) dominate the drive and drag currents (see log plots in Fig. 4), is a direct fingerprint of nonlocal cotunneling and its associated drag mechanism [54].

Finally, we estimate the magnitude of the drag current and comment on its experimental verification. Taking \( \Gamma_{\sigma} k_B T \sim 0.1U_{12} \), a drag current of the order of \( I_{drag} \gtrsim (U_{12} / |eV|)^2 \) pA is predicted for the cotunneling-assisted drag at \( eV_{sd} \gtrsim k_B T \max(2|\Delta_{10,01}|, |\Delta_{10,01,11}|) \). This is well within experimentally detectable currents and allows for a unique identification of the nonlocal cotunneling-driven drag via its distinct identifiers—i.e., the bias dependence in Eq. (10) and its fingerprints in bias spectroscopy [Fig. 4(d)]. While the high-bias cotunneling broadening of the drag region in Fig. 4(d) was recently observed in Ref. [33], the drag at low bias remains unexplored.

**Conclusions.**—In summary, we have identified a ratchetlike drag mechanism in CQDs, driven by nonlocal cotunneling processes. The key ingredient for the drag
become important at broadening and Kondo physics, which other coupling mechanisms between the QDs.

Evidence of the nonlocal cotunneling drag mechanism was became aware of a related experimental work in which Danish Research Foundation, Project DNRF103.

Nanostructured Graphene (CNG) is sponsored by the and comments on the manuscript. The Center for fruitful discussions, and K. Ensslin and D. Bischoff for clarifications on the experimental details in Ref.

We would like to thank J. Santos and N. A. Mortensen for fruitful discussions, and K. Ensslin and D. Bischoff for clarifications on the experimental details in Ref. and comments on the manuscript. The Center for Nanostructured Graphene (CNG) is sponsored by the Danish Research Foundation, Project DNRF103.

Note added.—While this work was under review, we became aware of a related experimental work in which evidence of the nonlocal cotunneling drag mechanism was observed at low bias in bias spectroscopy.
