Abstract

Evaluation of health related effects of beer intake is hampered by the lack of accurate tools for assessing intakes (biomarkers). Therefore, we identified plasma and urine metabolites associated with recent beer intake by untargeted metabolomics and established a characteristic metabolite pattern representing raw materials and beer production as a qualitative biomarker of beer intake. In a randomized, crossover, single-blinded meal study (MSt1) 18 participants were given one at a time four different test beverages: strong, regular and non-alcoholic beers and a soft drink. Four participants were assigned to have two additional beers (MSt2). In addition to plasma and urine samples, test beverages, wort and hops extract were analyzed by UPLC-QTOF. A unique metabolite pattern reflecting beer metabolome, including metabolites derived from beer raw material (i.e. N-methyl tyramine sulfate and the sum of iso- α -acids and tricyclohumols) and production process (i.e. pyro-glutamyl proline and 2-ethyl malate) were selected to establish a compliance biomarker model for detection of beer intake based on MSt1. The model predicted the MSt2 samples collected before and up to 12 h after beer intake correctly (AUC = 1). A biomarker model including four metabolites representing both beer raw materials and production steps provided a specific and accurate tool for measurement of beer consumption.

Keywords: Beer, Barley, Hops, Biomarker model, Hops, Metabolomics, Plasma, Urine, UPLC-QTOF

Introduction

Light to moderate alcohol consumption has been associated with decreased total mortality and with lower risk of metabolic diseases such as diabetes and cardiovascular disease^{1, 2}, but also with adverse effects on certain cancers³. The health related effects of consuming alcoholic beverages are mostly attributed to their alcohol content rather than specific components of different kinds of beverages, although there are some contradictory findings^{4, 5}. One of the major issues in alcohol research is the assessment in observational studies of the consumption of specific alcoholic beverages usually obtained using self-reported questionnaires. These tools may provide only moderately reliable information, since reporting may be influenced by cultural and personal views on alcohol. Biomarkers of food intake are powerful tools for assessment of dietary exposure in clinical and observational studies. Some recent studies suggested resveratrol and isoxanthohumol as intake biomarkers for wine and beer consumption, respectively^{6, 7}. However, resveratrol is also found in grapes and berries and isoxanthohumol has a highly variable rate of biotransformation into 8-prenylnaringenin (0-100% conversion) in the human gut making it a less than ideal biomarker^{8, 9}.

Beer is one of the most widely consumed beverages and is a very complex food with a metabolome originating from raw materials (e.g. barley and hops) and their transformation products formed during malting, boiling and fermentation. Consumption of beer may lead to direct absorption of its components but quite often their degradation or biotransformation products have also to be taken into consideration. Hops may be the most characteristic ingredient in beer and therefore the best candidate for single biomarker search strategies¹⁰. Iso- α -acids (IAAs) from hops, are specific to beer^{11, 12} yet one major issue with IAAs as biomarkers is their high susceptibility to degradation, leading to multiple products; therefore their quantity varies after storage^{13, 14}. In terms of metabolism of IAAs, only limited

1
2
3
4 number of studies is available^{15, 16}. Therefore investigating the fate of not only IAAs but also their
5
6 oxidation products in the human body would be a prerequisite for finding a suitable hops-derived
7
8 biomarker.
9

10 Basic steps and raw materials in beer production are mostly universal, yet production processes by
11
12 different producers vary, thereby further complicating the search for a global beer biomarker.
13
14 Furthermore, human individuals differ with respect to many biotransformation pathways, making it
15
16 even more challenging to find any single biomarker that is universal for beer intake. Finding markers
17
18 representing each common raw material and step in beer production and mapping their
19
20 biotransformation may therefore be a strategy to design more global aggregated biomarkers,
21
22 representing the complete process. Beer as well as alcohol may affect metabolism by altering the
23
24 glucose and insulin responses^{17, 18} and these parameters are therefore of potential importance as
25
26 modifiers of biomarker responses.
27
28
29
30
31

32 Metabolomics resulting from the development of highly sensitive modern analytical instruments is an
33
34 attractive tool for identification of novel intake biomarkers for specific diets, foods, food constituents
35
36 and/or for further assessment of their health impacts¹⁹⁻²². This technology together with chemometrics
37
38 also allows the identification of metabolite patterns as markers of intake¹⁹. Therefore, utilizing an LC-
39
40 MS based metabolomics and chemometrics approach we aimed here to identify the plasma and urinary
41
42 metabolites associated with recent beer intake and establish a novel and validated aggregated
43
44 biomarker produced by combination of identified metabolites that represent each of the raw materials,
45
46 processing steps, thereby ascertaining uniqueness to beer intake.

Materials and Methods

Subjects

37 healthy subjects within an age range of 18-60 years were recruited from the greater Copenhagen area by bulletins at educational institutions and on public websites for recruiting volunteers for clinical studies. Exclusion criteria were the following: systemic infections, psychiatric conditions and metabolic disease; alcohol intolerance; alcohol intake above the Danish Health and Medicines Authority's recommended limits of 7 and 14 units per week for females and males, respectively; donation of blood (>24 ml) less than 3 months before the study; breast feeding or pregnancy.

The subjects were given both verbal and written information about the study before providing their written consent. The study was carried out at the Department of Nutrition, Exercise and Sports, Faculty of Science, University of Copenhagen, Frederiksberg, Denmark. The research protocol was approved by the Ethical Committee of the municipalities of Copenhagen and Frederiksberg (H-1-2013-029) and the study has been registered at clinicaltrials.gov (NCT02449577).

Study Designs and Diets

Meal study 1(MSt1): 19 subjects were included in the main part of the study. A formal power calculation is not possible for explorative studies but several previous meal studies have indicated that 10-20 volunteers suffice. The study was performed as a randomized, crossover, single-blinded intervention with four study periods of three days and a wash-out period of >1 week between periods. The four periods consisted of a test day where subjects were served with one of the three different test beers or a control beverage in randomized order. The three test beers were a strong lager (SB) (Carlsberg Elephant, 8 % ABV, ~35 IBU), a regular lager (RB) (Carlsberg Pilsner, 4.6 % ABV, ~22

1
2
3
4 IBU), and a light/alcohol-free beer (LB) (Tuborg Super Light 0.1 % ABV, ~19 IBU). The control soft
5
6 drink beverage (C) (Carlsberg Sports drink) was alcohol free but with the same energy content
7
8 (carbohydrate and protein) as the average of the test beers.
9

10
11
12 The evening before the test day, subjects consumed a standardized dinner (spaghetti Bolognese) with
13
14 water *ad libitum*. On the test day, after having a standardized breakfast (bread, butter, ham, cheese,
15
16 orange juice) *ad libitum* between 7-8 am, subjects were instructed to fast for 3-4 hours (except for ~½
17
18 liter of water). Subjects were served a standardized lunch of Parisian toast/grilled cheese sandwiches
19
20 (Tulip Food Company) at 11.35 am together with one of the test beers or the C (330 ml), all to be
21
22 consumed within 25 min. The amount of toast was adjusted according to the type of drink served, so
23
24 that the content of macronutrients was the same in each meal. Until 2.35 pm (last blood sampling)
25
26 subjects did not consume any food or drink, but had water *ad libitum*. Thereafter, subjects were
27
28 allowed to consume their habitual diet but were instructed to abstain from intake of alcohol in any form
29
30 for 24 hours after the start of each test day (i.e. until 8 am in the following morning). They were
31
32 otherwise instructed to retain their usual pattern of alcohol intake during the remaining 4 weekdays
33
34 between each of the four test periods.
35
36
37
38
39

40
41 *Meal study 2(MSt2)*: Four subjects were included in a second (validation) study; one of them also
42
43 participated in the MSt1. The study was performed as a randomized, crossover intervention with all the
44
45 same details as for MSt1, except that only two study periods of three days were conducted. The two
46
47 periods consisted of a test day where subjects were served with two servings (660ml) of either of the
48
49 two test beers in randomized order. Two test beers were used; one being a high hops moderate alcohol
50
51 beer (HHB) (Lawn Mower, Carlsberg breweries, Sweden, 4.8 % ABV, ~31 IBU) and the other a low
52
53 hops high alcohol beer (LHB) (T-beer, Tuborg breweries, Romania 7-8 % ABV, ~8 IBU). These beers
54
55
56
57
58
59
60

1
2
3
4 were selected as extremes with regard to the two main raw materials in beer to serve as a test for the
5
6 validity of the biomarker development concept.
7
8

9
10 On the test day volunteers in the MSt2 validation study had a standardized breakfast and lunch
11
12 (multigrain bread containing also barley, cheese, ham, a red pepper fruit, radishes, apple, banana,
13
14 orange juice and egg) according to calculated energy needs, and consumed the same standardized
15
16 dinner together with 660 ml of either of the test beers. The following day, they consumed the same
17
18 standardized meals but not the test beers.
19
20
21

22
23 In both studies volunteers were allowed otherwise to remain on their habitual diets, but were required
24
25 to abstain from drinking all forms of alcohol and avoid heavy physical activity from 48 and 24 hours
26
27 before the test days, respectively.
28
29

30
31 A simple randomization was used in both studies. The brewery delivered the four drinks in dark bottles,
32
33 marked A, B, C, D for MSt1 and E and F for MSt2. A sequence table was generated for all volunteers
34
35 so that they received the drinks in random order within each study. In principle participants, care
36
37 providers and assessors were all blinded, however the participants could easily taste the nature of the
38
39 soft drink. They were instructed not to tell the care providers.
40
41
42

43 **Blood and Urine Sampling**

44
45
46 Blood samples were drawn only in MSt1 on each test day 20 min before (baseline) and 0.45, 2 and 3 h
47
48 after the subjects consumed the test beverages together with a standardized lunch. The blood samples
49
50 were transferred into 4 mL vials containing heparin as an anticoagulant. The blood was centrifuged at
51
52 3,000 g, 4°C for 10 min. The plasma fraction was aliquoted into 2 mL cryotubes and stored at -80°C
53
54 until further processing.
55
56
57
58
59
60

1
2
3
4 Urine samples were collected on each test day within the following time periods: from their morning
5 void until 20 min before having their test drink (baseline); from baseline until 1.5 h; from 1.5 h to 3 h;
6
7 and from 3 h to 21 h. In addition, 24 h pooled samples were created as a mixture of the urine samples
8
9 collected in the four different time intervals in relative proportion to their volumes.
10
11

12
13
14 For the MSt2, only urine samples were collected: from lunch to dinner before having the test beer
15 (baseline), baseline to 2 h, 2h to 4 h, 4h to 12 h, 12 h to 24h and 24 h to 40 h.
16
17

18
19
20 During sampling, urine was stored below 5 °C in cooling bags and after completion, sample aliquots
21
22 were kept at -80 °C until further analysis.
23
24

25 26 **Blood glucose and serum insulin**

27
28
29 The blood samples were collected in dry tubes for the measurement of insulin and in fluoride citrate
30 tubes for the measurement of glucose. Plasma glucose was measured with an enzymatic colorimetric
31 method (ABX Pentra Glucose HK CP; Horiba, Montpellier, France) and analyzed with an ABX Pentra
32
33 400 (Horiba). Serum insulin was measured by a chemiluminescent immunometric assay with an
34
35 Immulite 1000 Immunoassay System (Siemens Healthcare Diagnostics, West Sacramento, CA). All
36
37 samples were analysed in one batch. Intra-assay and interassay coefficients of variation (CVs) for
38
39 glucose and insulin were below 2.8%.
40
41
42
43
44

45 46 **UPLC-QTOF Analysis**

47
48
49 Plasma protein precipitation, urine centrifugation and dilution procedures were performed as described
50
51 previously^{23, 24}. The 288 plasma samples and 320 urine samples were placed in 96-well plates, such
52
53 that all samples (urine or plasma) from the same individual were in the same plate (analytical batch)
54
55
56
57
58
59
60

1
2
3
4 while the individuals were randomized between batches (five per batch) and the order of samples was
5
6 randomized within each batch. An ultra-performance liquid chromatography (UPLC) system coupled to
7
8 a quadrupole time-of-flight mass spectrometer (Premier QTOF, Waters Corporation, Manchester, UK)
9
10 was used for sample analysis. The mobile phase was 0.1% formic acid in water (solvent A) and 0.1%
11
12 formic acid in 70% acetonitrile and 30% methanol (solvent B). Five μL of each sample were injected
13
14 into a HSS T3 C18 column (2.1 x 100 mm, 1.8 μm) coupled with a VanGuard HSS T3 C18 column (2.1
15
16 x 5mm, 1.8 μm) and the gradient was operated for 7.0 min. The eluate was analyzed by electrospray
17
18 ionization (ESI) in positive and negative mode, applying a capillary voltage of 3.2 kV and 2.8 kV,
19
20 respectively and cone voltage of 20 kV. Ion source and desolvation gas (nitrogen) temperatures were
21
22 set to 120 and 400 $^{\circ}\text{C}$, respectively. More detail on UPLC-QTOF analysis conditions can be found
23
24 elsewhere²⁵. Blanks (5% of acetonitrile:methanol 70:30 v/v in water) and external metabolomics
25
26 standard mixtures were injected after every 30 samples, throughout each analytical batch²⁵.
27
28
29
30
31
32

33
34 In addition to plasma and urine samples, the test drinks, a beer wort extract, and hops extracts were
35
36 analyzed with UPLC-QTOF using identical conditions. Sample preparation was comprised of dilution
37
38 in solvent A for test drinks and wort whereas a mixture of solvent A and B (50-50 %) was used for
39
40 dilution of the hops extract.
41
42

43
44 MS/MS fragmentation experiments were conducted for structural characterization of beer intake
45
46 markers. The collision-induced dissociation (CID) was set to 10, 20 and 30 eV in separate runs and all
47
48 other parameters were kept as for the MS full scan experiments as described above.
49
50

51 52 **Data Preprocessing**

53
54
55
56
57
58
59
60

1
2
3
4 Initially, raw data were converted to intermediate MZdata using an R function (convert.waters.Rd,
5 <https://github.com>) operating on R software (ver. 3.1.0.). MZdata files were imported into MZmine
6
7 2.10 for data preprocessing including the following steps: mass detection, chromatogram builder,
8
9 chromatogram deconvolution (local minimum search), isotopic peaks grouper, peak alignment (join
10
11 aligner), duplicate peak filter, peak list row filter and gap filling (peak finder). The term ‘feature’ is
12
13 used to refer to an ion with a specific retention time and mass over charge ratio (m/z) throughout this
14
15 paper.
16
17
18
19

20
21 MZmine-preprocessed data were imported into MATLAB R2013a (ver. 8.1.0.604). Feature filtering
22
23 was applied based on three criteria. First, the features detected earlier than 0.3 min and later than 6 min
24
25 were removed. Second, if a feature has a significant peak area (>60, approx. 6 times the maximal
26
27 background noise) in the first blank sample in at least one of the analytical batches, the feature was
28
29 removed from the entire set as background noise. Third, if a feature had a peak area lower than 10
30
31 (considered as noise level or gap filling errors), in more than 60% of the samples within every sample
32
33 group (specified with one test drink type and one time point), the feature was excluded (percent rule).
34
35
36
37
38

39 Urine samples were normalized to unit-length normalization to correct for urine concentration
40
41 variations. Later, to remove inter-batch variation, each feature detected in urine/plasma samples within
42
43 each batch was divided with the overall mean of its recordings included in the entire batch. This
44
45 approach is justified by randomization of individuals between batches and of all samples from each
46
47 individual within the same batch prior to analysis. Application of these pre-processing and
48
49 normalization procedures separately on negative and positive mode data was followed by concatenation
50
51 of the datasets from the two modes. In order to ease identification, features within the retention time
52
53
54
55
56
57
58
59
60

1
2
3
4 range of 0.02 were grouped and assigned as one feature group if they had correlation coefficients
5
6 higher than 0.7. Then, each feature group is considered as representation of one unique compound.
7
8

9 10 **Data Analysis**

11 12 13 **ASCA**

14
15
16 Data analysis was performed in MATLAB R2013a (ver. 8.1.0.604). For the plasma samples the
17
18 baseline level of each feature was subtracted from its subsequent recordings at each time point (0.45, 2
19
20 and 3 h) in order to reduce the influence of intra-individual factors. For urine, this procedure did not
21
22 affect the outcome and was therefore omitted (data not presented).
23
24

25
26 Unit scaled data were subjected to, ASCA (ANOVA Simultaneous Component Analysis)²⁶, to isolate
27
28 and further investigate the variation related to test drinks and to identify the contributions of time
29
30 course and test drink \times time interactions.
31
32

33
34 In order to evaluate the significance of ASCA decomposed effect matrices, a permutation test was
35
36 employed²⁷. The permutation test is based on comparison of sum of squares (SS) of each effect matrix
37
38 with SS distribution of matrices obtained with repeated random permutation of class labels. In this
39
40 case, the number of permutations was 100,000. The significance of each effect matrix was determined
41
42 as the fraction of data permuted matrices that had SS higher than the SS of the original effect matrix.
43
44
45

46
47 Later, simultaneous component analysis (SCA) was applied on individual effect matrices to interpret
48
49 the associated variation. SCA provides information only on the level averages, and to analyze the
50
51 variation between samples within each level, the residuals were projected on the principal component
52
53 subspace of effect matrices, as described previously²⁸.
54
55
56
57
58
59
60

1
2
3
4 An approach similar to ANOVA-PCA was carried out, where the residual matrix was added to test
5
6 drink effect matrix^{20,28}. This provided the basis data matrix for the subsequent PLSDA.
7
8

9
10 ASCA was performed with in-house developed MATLAB functions.
11

12 13 **PLSDA**

14
15
16 PLS_Toolbox (version 6.5, Eigenvector Research, Inc., MA, US) was used for partial least squares
17
18 discriminant analysis, PLSDA. PLSDA was applied to differentiate the plasma and urine metabolic
19
20 patterns associated with beer intake (i.e. SB+PB+LB vs. C) within the consumed beers. In order to
21
22 validate PLSDA models, ten different test sets each comprised of data from all samples (time points
23
24 and treatments) from all possible combinations of two subjects were set aside. Variable selection was
25
26 performed repeatedly by removing variables with selectivity ratio and variable importance in projection
27
28 (VIP) values lower than 1 until no further increase in the cross-validation (eight-fold) classification
29
30 errors could be observed. Final models with selected variables were evaluated using test set
31
32 misclassification²⁹. The variables that were selected in at least seven of the models were assigned as
33
34 markers of beer intake.
35
36
37
38
39
40

41 **Calibration and validation models**

42
43
44
45 The calibration set was created from MSt1 including only the measurements of the selected metabolites
46
47 for urine collected at 0-1.5 h, 1.5-3 h and 3-21 h. PLSDA was applied on the calibration set to
48
49 discriminate the three beers (SB+RB+LB) from the soft drink, C. PLSDA models were built with 1 to 5
50
51 LV and optimum model complexity (i.e. number of components) was decided by evaluating
52
53 misclassifications. This PLSDA model is used as the calibration model. MSt2 with the measurements
54
55
56
57
58
59
60

1
2
3
4 of selected metabolites for four subjects was used as the test set to validate the calibration model. The
5
6 evaluation was based on how well the calibration model performs in classifying MSt2 samples
7
8 collected after beer intake within the beer periods (i.e. SB+RB+LB in MSt1), as well as classifying
9
10 MSt2 samples collected before beer intake within C (MSt1). Models were assessed by diagnostic
11
12 statistics, area under receiver operating characteristic curve (AUC) and misclassification rate.
13
14
15
16

17 **Standards and Identification**

18
19
20 Four levels of chemical identification according to the published guidelines for chemical analysis were
21
22 used³⁰. Amino acids (i.e., tyrosine, leucine/isoleucine, proline) and the dipeptide pyroglutamyl proline
23
24 (pGlu-Pro) were identified using an in-house metabolite database containing retention time information
25
26 and MS spectra of reference substances. Reference standards for ICS-I3 (containing 62.3 % w/w of
27
28 trans-IAA) and ICE-3 (containing 44.64 % w/w of AA) were obtained from Labor Veritas (Zurich,
29
30 Switzerland). Isoxanthohumol and naringenin were purchased from Sigma (Schnelldorff, Germany).
31
32 For unknown compounds with a signal area higher than 600, MS/MS spectra (10, 20 and 30 eV) were
33
34 recorded in order to obtain fragmentation information to compare with data in available databases, such
35
36 as Metlin (<https://metlin.scripps.edu>), hmdb (<http://www.hmdb.ca>), ChEMBL
37
38 (<http://chembank.broadinstitute.org/welcome.htm>), Chemspider (<http://www.chemspider.com>), and
39
40 similar sites. All six test drinks and beer wort and hop extract were kindly provided by Carlsberg A/S.
41
42
43
44
45
46

47 **NMR analysis**

48
49
50 The presence and identity of the dipeptide pGlu-Pro in beer was verified by 2D homo- and
51
52 heteronuclear high-resolution NMR spectroscopy using beer fractionated by preparative UPLC. To this
53
54 end, lyophilized UPLC fractions containing compound with a mass consistent with possible pGlu-Pro
55
56
57
58
59
60

1

15

16 17 **Selection of the aggregated biomarker for beer intake**

18
19
20 Initially, the origin of each compound associated with beer intake was grouped based on their origin.
21
22 This is accomplished by comparing m/z and retention time of each beer marker with m/z and retention
23
24 time of the compounds detected in test beers, hops extract and wort reference samples. Accordingly,
25
26 beer intake markers were divided into four groups, originating from (1) hops, present only in hops
27
28 extract and test beers, (2) wort, present only in beer wort and test beers, (3) fermentation related
29
30 markers, present only in beer but not in hops or wort, (4) human metabolism of beer components,
31
32 present only in urine and plasma but not in beers, wort or hops. Since beer is a processed and complex
33
34 beverage, none of the markers originating from beer raw materials or their processing individually may
35
36 suffice as sufficiently specific and sensitive beer intake biomarkers. An aggregated biomarker
37
38 combining each raw material and process was therefore constructed based on the principle that each
39
40 included biomarker must be identified chemically and present as a signalling exposure marker clearly
41
42 increasing after intake of each kind of beer while having much smaller or undetectable levels in the
43
44 control period.
45
46
47
48
49
50

51
52 The calibration set for this aggregated biomarker was built from MSt1 including only the
53
54 measurements of the four selected metabolite groups in the 24 h pooled urines from each period and
55
56
57
58
59
60

from each of the 18 subjects. A PLSDA model with one component was established as the calibration model. The performance of the calibration model was evaluated using metabolome profiles from MSt2 (validation set), which had not been used in model development and optimization. The validation set included the measurements of the four selected metabolite groups in urine samples collected before (as control) vs. 0-2 h, 2-3 h and 3-12 h after beer intake (representing beer intake) for all four individuals.

Results

Recruitment started April 2013 and the trials ended November 2013. A total of 18 completers in MSt1 were included in the analyses. One subject dropped out after the first out of four periods, because she did not have enough time to participate anymore. All four completers in MSt2 were included. Data acquisition ended in August 2014. The trials ended as scheduled. We report here only the primary and some secondary aims according to the protocol. Baseline characteristics of the subjects are recorded in Table 1. No adverse events for the trial were recorded.

Table 1. Participant characteristics of MSt1 and MSt2 at the time of enrollment

	MSt1 (n = 19)	MSt2 (n = 4)
Female [n (%)]	9 (47)	2(50)

Blood Pressure (mm Hg)		
Systolic blood pressure	110.2±6.5	113.7±8.1
Diastolic blood pressure	62.0±8.0	75.7±11.4
Habitual Alcohol Consumption ¹ [n]		
<i>Moderate (1-2 drink/day)</i>	11	2
<i>Low (or abstained) (<1 drink/day)</i>	7	2

¹The levels of alcohol consumption is adapted from on NIH

Fasting whole-blood glucose and serum insulin levels were not different between treatments. There were no significant differences between treatments when glucose and insulin response were expressed in terms of total or incremental AUC.

Selection of metabolites associated with beer intake

The number of samples for plasma was 216 (i.e. 18 subjects \times three time points \times four test drinks) and 360 for urine samples (i.e. 18 subjects \times (four time points + pool) \times four test drinks). A total of 1503 and 8935 features remained after feature filtering for plasma and urine samples, respectively.

ASCA partitioned the total variation into contributions of corresponding experimental factors (i.e. test drink and time) and their interaction. A permutation test was applied in order to validate the ASCA factor models. Comparing the SS of 100,000 random class assignments with SS calculated from the original classes for each effect matrix, revealed that only the two main effects, time and test drink, were significant ($P < 0.0001$), but not the interaction between time and test drink ($P > 0.7$) (Figure S-1 and S-2). The percentage of explained variation of each factor was calculated as the SS of decomposed factor matrices (Table S-1).

SCA scores plot (Figure 1) displays the separation of the samples at the test drink level both for urine and plasma. For urine, the separation of beer samples was mainly explained by PC1, with lower PC1 score values for beer samples compared to C. On the other hand, for plasma the dominating factor was alcohol, explained by PC1, and the combination of PC1 and PC2 provides the separation of beer intake.

SCA scores plots for individual factors and their interaction are also given in Supplemental Material (Figures S-3 and 4).

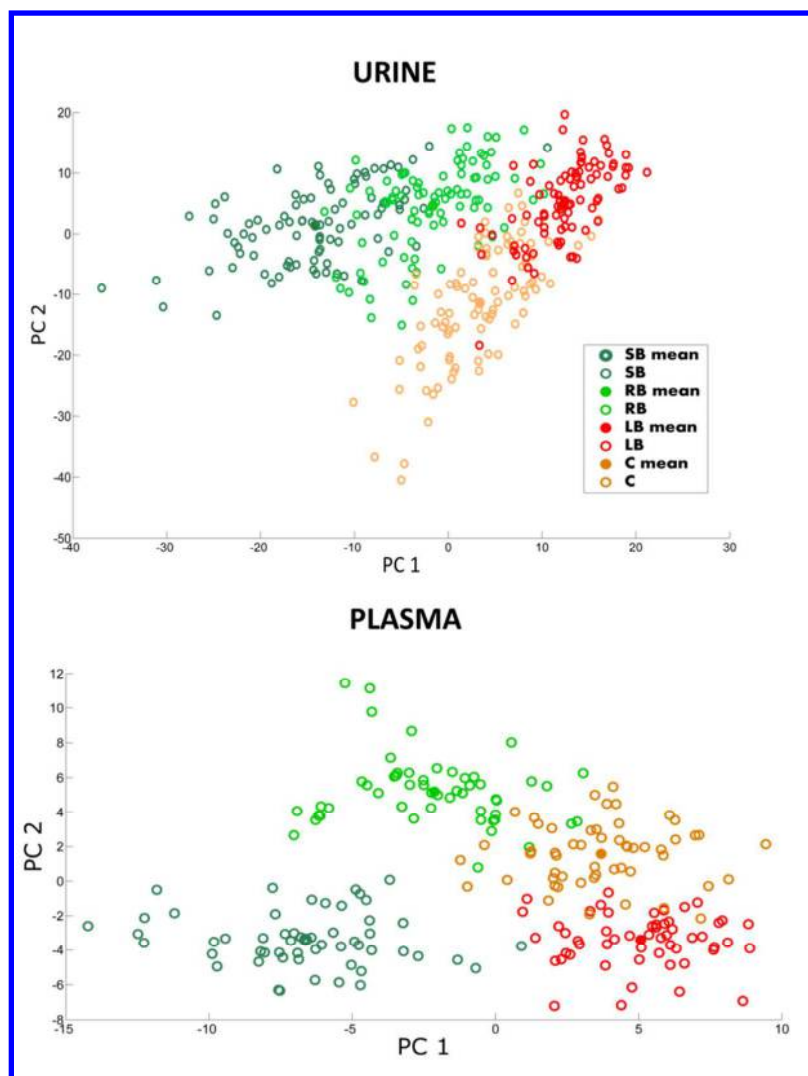

Figure 1. SCA score plot of the test drink matrix for both the urine (top) and plasma (bottom) metabolic profiles. An SCA model was applied to the effect matrix obtained from the ANOVA decomposition.

PLSDA was applied on the matrix where residuals were added to the decomposed test drink factor matrix. Three beers are assigned as one group providing a binary classification problem (i.e. SB+PB+LB vs. C). The mean of misclassification errors of selected test sets for plasma and urine were significantly higher than classifications errors of 1000 random class assignments (P-values were 0.04

for plasma and 0.004 for urine). The potential beer intake markers were selected by evaluating VIP values and selectivity ratio.

Assessment of the origin of putative beer intake biomarkers

Sixty nine compounds associated with beer intake were grouped based on their presence in test beers, wort and hops extracts as described in the Materials and Methods section. This comparison revealed 15 compounds originating directly from the hops extract (two in both plasma and urine, 13 only in urine), 19 directly from wort (one in both plasma and urine, three only in plasma, 14 only in urine), 2 from fermentation (only observed in urine) and 20 from human biotransformation (one only in plasma and 19 only in urine). The identified compounds are given in Table 2 and the list of unknown compounds and their source is given in Table S-2.

Table 2. Identified plasma and urine metabolites originating from beer raw materials hops and wort, fermentation process and human and/or microbial biotransformation of beer components.

Identification of metabolites associated with beer intake.

1
2
3
4 *Metabolites originating from hops*: The identified metabolites originating from hops were IAAs and
5 their oxidation and degradation products (Table 2, Metabolites 1 to 11). Detailed description of
6 identification based on MS/MS is provided in the Supplementary material (Text S-2, Figure S-5 and S-
7 6). IAAs, iso-cohumulone and the mixture of iso-humulone and iso-adhumulone were identified as
8 markers of beer intake both in urine and plasma with very similar excretion profiles. Figure 2 illustrates
9 the excretion profiles of iso-cohumulone after consumption of 330 mL of test drinks. In accordance to
10 the measured IAA concentrations in test beers (Figure 2C), IAAs in urine and plasma were the highest
11 following consumption of SB. In plasma they dropped rapidly within 3 h, on the other hand, IAAs
12 peaked later in urine (pooled urine within 1.5-3 h) and were still present in urine collected from 3 h up
13 to 21 h.

1
2
3
4 *Metabolites originating from human metabolism:* Major metabolites were related to IAA
5 biotransformation products and the same conjugates were recorded both for iso-cohumulone and iso-
6 ad/humulones (Table 2, Metabolites 12 to 23). Three related groups of conjugates were observed with
7 addition of 29.98 Da (equal to addition of NO or CH₂O; metabolites 12 and 13), 45.98 Da (equal to
8 NO₂ or CH₂O₂; metabolites 14 and 15) and 166.99 Da (metabolites 16 and 17) to iso-cohumulone and
9 iso-ad/humulone. We speculate that these metabolites are oxidation and methylation products as well as
10 cysteine adducts of isocohumulone and iso/adhumulone. Urinary excretion profiles of the IAA
11 conjugates were similar to those of IAAs (Figure 2). Metabolites 15 and M16 were still present at high
12 levels in urine collected between 3 and 21 h, indicating that the peak of excretion of those metabolites
13 was later than 3 h after intake (Figure S-8).

25
26
27
28

29 Metabolites 18 to 22 (Table 2) were products of phase II metabolism (glucuronides and sulfates) based
30 on their fragmentation patterns, yet the identity of the biotransformed beer components remains
31 unknown. Metabolites 20 to 22 were phase II (glucuronide and sulfate) metabolites of the same
32 compound and their fragmentation pattern revealed the presence of a thiol group. Furthermore, one
33 cysteine mercapturic acid conjugate (Metabolite 23) is detected as a urinary marker. In terms of
34 excretion profiles, all of them peaked in urine collected within 1.5 to 3 h. The products were not
35 specific to the beer intake as they were also present after intake of C, albeit at much lower levels
36 (Figure S-8).

45
46
47
48

49 *Metabolites originating from wort and fermentation:* The identified metabolites are given in Table 2
50 (Metabolites 24 to 30). The only metabolite originating from wort that is detected in both urine and
51 plasma was pGlu-Pro. NMR based structure elucidation of pGlu-Pro is described in Figure S-9. The
52 urinary excretion profile is given in Figure 3A with the highest excretion level around 3 h following
53
54
55
56
57
58
59
60

1
2
3
4 beer intake. The pGlu-pro was also detected in urine samples prior to the test meals and did not
5
6 fluctuate following the consumption of C drink, indicating that it probably is a constituent of foods
7
8 other than beer/wort or even that it is formed endogenously, but levels after beer intake are
9
10 significantly higher. Hordenine, maltose (or an isomer) and NMT sulfate are identified as markers of
11
12 beer intake in urine. Hordenine had already reached its maximum excretion level 0-1.5 h after intake,
13
14 whereas maltose and NMT sulfate peaked in urine collected between 1.5-3 h and 3-21 h, respectively
15
16 (**Figure 3B**, Figure S-10). Hordenine and NMT were present in the urine of the a few subjects prior to
17
18 beer intake albeit with lower levels.

Figure 3. Urinary excretion profiles of pGlu-pro (A), NMT sulfate (B) and 2-ethyl malate (C).

In plasma, isoleucine, leucine and tyrosine are identified as metabolites originating from wort and associated with beer intake. The excretion profile of tyrosine is shown in Figure S-11, in agreement with tyrosine concentration in beer. Both tyrosine and isoleucine/leucine were observed as rapidly absorbed metabolites.

1
2
3
4 In relation to fermentation, 2-ethyl malate is identified as a metabolite associated to beer intake in
5 urine. It is excreted rather late compared to metabolites from hops and wort, with a reasonable high
6 excretion between 3-21 h (Figure 3C).
7
8
9

10 11 12 **Selection of metabolites for the aggregated beer biomarker**

13
14
15
16 None of the beer intake markers discovered in this study was sufficiently specific or sensitive as single
17 biomarkers to assess beer intake. The major issue with metabolites originating from hops (e.g. IAAs) is
18 not specificity (see baseline levels, Figure 2) but sensitivity because they are not stable and several
19 degradation products were also identified in urine at varying amounts. The issue with metabolites
20 originating from wort or fermentation was that they were observed as markers of effect rather than
21 exposure in the sense that they were present already at baseline but increased following beer intake.
22 Hence none of the markers identified are specific to beer intake *per se* (see baseline levels, Figure 3).
23
24 For the aggregated beer intake biomarker we selected one metabolite from each raw material (hops and
25 barley) and production process (malting and fermentation) and established a compliance biomarker
26 model for detection of beer intake based on MSt1. To overcome the issue with variable degradation of
27 IAAs as representative of hops derived metabolites we used the sum of iso-cohumulone and iso-
28 ad/humulones and their major degradation products, tricyclohumol and tricyclohumol. NMT sulfate
29 was selected representing barley and pGlu-pro to represent heat treatment during malting. Fermentation
30 was represented by 2-ethyl malate since this compound is not removed in de-alcoholization processes
31 to produce light and non-alcoholic beers.

51
52
53 Figure 4 demonstrates how the calibration model performs in terms of distinguishing samples after beer
54 intake from the control time points and/or periods for calibration and validation sets. The scores plot of
55
56
57
58
59
60

the first component (Figure 4A) demonstrates that the calibration model provides correct prediction of the classes as control and beer groups for the samples from MSt2 (open circles in Figure 4A) for urine collected up to 12 h. Testing the same calibration model on urine samples collected from 12 to 24 h (MSt2), resulted in 0 sensitivity such that all the samples collected more than 12 hours after beer intake were wrongly classified as control samples (Figure S-12). This suggests that metabolites associated with beer intake were already excreted at 12 h. Therefore, the calibration model is valid for detection of beer intake up to 12 h post consumption as well as in 24 h pooled urine samples.

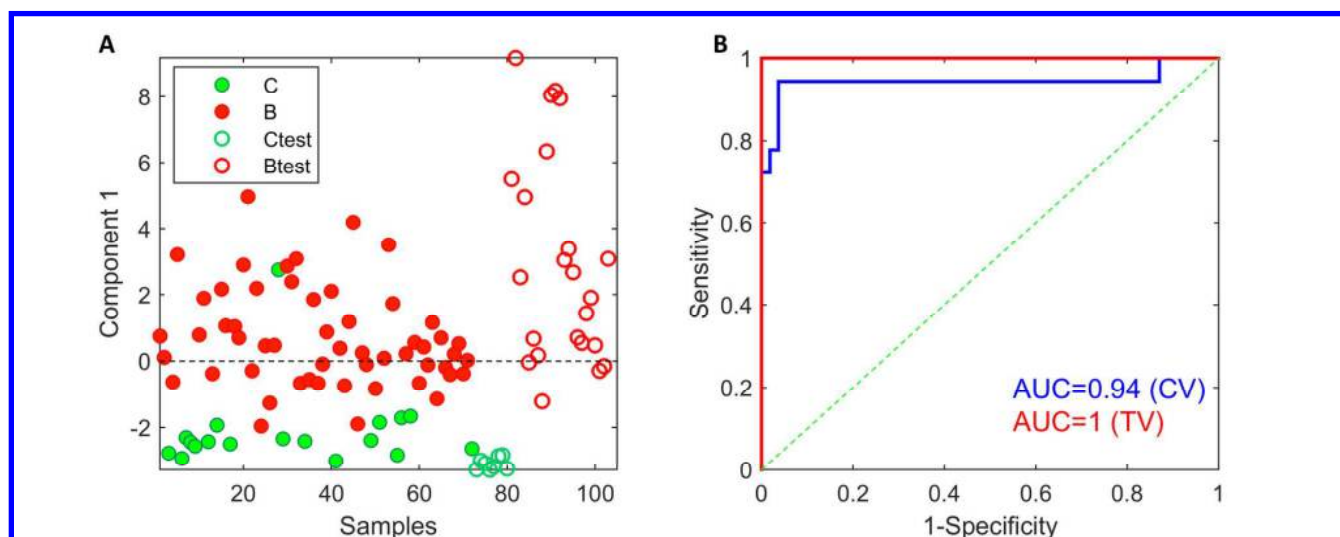

Figure 4 (A) PLSDA scores plot of the first component. The calibration model is developed using the measurements of four metabolites for samples from the meal study 1 (filled circles) and the model is tested with samples from meal study 2 (open circles). C and B refer to control samples and 24 h pooled samples from the meal the meal study 1, respectively. Ctest and Btest refer to the samples before and collected up to 12 h following beer intake from meal study 2 (B) ROC curve describing the performance of the PLSDA model in terms of predicting beer intake for calibration (CV) and test set (TV) samples, respectively.

1
2
3
4 In order to assess the importance of each metabolite, we removed one of the four metabolites at a time
5
6 and the calibration model still performed efficiently in terms of separating beer drinkers from control,
7
8 thus none of the metabolites is individually crucial for the prediction.
9
10

11 12 **Discussion**

13
14
15
16 Accurate assessment of food intake is central in nutrition research and identification of specific food
17
18 intake biomarkers is therefore a promising way ahead. Finding single biomarkers for complex foods
19
20 like beer is difficult because each component in the food may be used also in other foods. The strategy
21
22 described in the current study is therefore to derive aggregated biomarkers for complex foods adding
23
24 the best markers for each component and processing step to improve the resulting biomarker specificity
25
26 and sensitivity. Our cross-over meal study provided many markers associated with recent beer intake,
27
28 particularly in urine, reflecting the metabolomes of beer, as well as metabolites originating from their
29
30 human metabolism (Table 2). Beer metabolome is characterized by compounds originating from its raw
31
32 materials, barley and hops, and their transformation products derived upon malting and fermentation.
33
34 Each of the raw materials and processes flag specific compounds in urine and plasma. However, these
35
36 are either present in other foods or unstable. Therefore individually they lack the specificity and
37
38 sensitivity needed for intake biomarkers.
39
40
41
42

43
44 IAAs from hops have been previously suggested as biomarkers of beer intake as they are specific to
45
46 beer^{11, 12, 31}. Although IAAs provided high sensitivity and specificity for detection of beer intake up to
47
48 21 h for MSt1, they were not even detected after intake of low hops beer (MSt2). This is attributed not
49
50 only to the low hops content of the test beer but also to formation of several oxidative degradation
51
52 products of IAAs^{32, 33} underlining their instability. Tentatively identified degradation products of *trans*-
53
54 IAA in urine were tri- and tetra-cyclohumenes and tri-cyclohumols^{14, 34} whereas, mono- and di-
55
56
57
58
59
60

1
2
3
4 hydroxylated humulones and humulinones appeared as oxygen-dependent degradation products of both
5
6 *cis*- and *trans*-IAAs³³. Indeed, only tricyclohumols were detected in low hops beer (MSt2), which has
7
8 also been shown previously to be one of the major degradation products³⁴. Therefore, using IAAs as
9
10 single biomarkers of beer intake is not feasible since consumption of longer-term stored beers and beer
11
12 varieties with low hops content may result in total degradation and therefore to low sensitivity for
13
14 assessment of beer intake. Instead, the sum of IAAs and their major degradation products (e.i. tri-
15
16 cyclohumols) as a single biomarker provides a better predictor of beer intake as potential loss of IAAs
17
18 is partially compensated by formation of tri-cyclohumols. Although validating this biomarker in MSt2
19
20 provided high sensitivity and specificity (AUC =1), further studies including diverse types of beer and
21
22 different storage periods are required for final validation. Our results also suggest that after ingestion
23
24 IAAs are oxidized into metabolites, which could be tentatively identified based on fragmentation
25
26 patterns (Table 2). The oxidized IAA metabolites are compounds similar to products of degradation
27
28 during storage³⁵. It is difficult to discriminate between phase I metabolism and storage-induced
29
30 oxidation of IAA as the products have very similar structural characteristics but IAA oxidation is much
31
32 accelerated after ingestion indicating enzyme-mediated formation. Oral administration of IAAs to
33
34 rabbits lead to recovery of less than 6% of the dose as such metabolites, suggesting that IAAs may also
35
36 be subject to other kinds of metabolism¹⁶. Indeed, we observed unidentified conjugation products of
37
38 IAAs formed from oxygenated IAAs by methylation and cysteine conjugation. Further isolation and
39
40 structure elucidation is required to verify these structures. Some beer brands use hydrogenated hops
41
42 extracts, which renders the IAAs more stable, however it is uncertain whether these are used
43
44 exclusively since their organoleptic properties do not exactly match those of the normal hops extract³⁶.
45
46 Adding markers for these compounds might be needed to cover some more unusual brands of beer.
47
48
49
50
51
52
53
54
55
56
57
58
59
60

1
2
3
4 The wort-derived beer intake markers were present in barley or formed during the malting/boiling
5 process; therefore they may also be found in other barley containing foods, limiting their specificity.
6
7 pGlu-pro was increased after beer intake, potentially due to a high content of proline in barley. pGlu-
8 pro may be formed upon heating of the barley sprouts during malting or wort boiling. Pyroglutamyl
9 peptides have been suggested to act on inflammatory diseases^{16, 37, 38} and have been shown to exhibit an
10 antidepressant-like effect in mice³⁹. To our knowledge, pGlu-Pro has not previously been observed in
11 beer samples or associated with an increase in blood or urine after beer intake. The sulfate conjugate of
12 NMT is another wort-derived compound, potentially formed through phase II metabolism in the plant
13 or during the malting process. NMT is produced by N-methylation of tyramine, which is further
14 methylated to hordenine⁴⁰. Hordenine is suggested as a qualitative marker of beer intake⁴¹, yet its
15 excretion profile after intake of other barley containing foods should be investigated since it may not be
16 possible to discriminate beer intake from intake of other barley containing diets.
17
18

19
20
21 Malic acid, particularly in the form of di-ethyl malate is widely described as a constituent of alcoholic
22 beverages^{42, 43}, yet according to our knowledge, 2-ethyl malate has not previously been described in
23 beer. We could also confirm its presence in wine and cider samples (data not shown), indicating that it
24 is not specific to beer but to fermented beverages. 2-ethyl malate is probably formed through
25 esterification of malic acid with ethanol, followed by partial rearrangement⁴⁴ indicating that non-
26 alcoholic food fermentation is probably not a source of its formation.
27
28

29
30
31 NMT sulfate, pGlu-pro and 2-ethyl malate were each detected in the urine of some subjects prior to
32 intake of the test drink, suggesting intake from other food sources. Therefore, none of the single
33 metabolites were sufficiently sensitive and specific for assessment of beer intake. Yet an aggregated
34 biomarker characterizing the beer metabolome (i.e. its raw materials and the malting and brewing
35 processes) provided a unique pattern. The four metabolites - NMT sulfate originating from barley, 2-

2
3
4 ethyl malate originating from fermentation, pGlu-Pro originating from malting, and the sum of IAAs
5
6 and their major degradation products (tricyclo-co- and -ad-humols) originating from hops – were used
7
8 to establish an aggregated biomarker. It is crucial to validate new biomarkers with independent
9
10 controlled trials as well as samples from observational studies⁴⁵. Therefore, we utilized MSt2 for
11
12 validation of the calibration model. The calibration model efficiently predicted beer intake up to 12 h
13
14 (AUC = 1, Figure 4B); this set of four metabolites therefore provides an excellent aggregated
15
16 biomarker for detection of beer intake. When we removed any one of the four metabolites from the
17
18 aggregated biomarker, the calibration models performed equally well, suggesting that none of the
19
20 individual metabolites are crucial for the model and that the aggregated approach is very robust.
21
22

23
24
25 Other compounds originating from hops, such as reduced derivatives of IAAs and prenylated phenols
26
27 have been suggested previously as urinary and blood biomarkers of beer intake^{13, 31, 46}. Isoxanthohumol
28
29 was shown to be stable even after 10 years of storage, making it a suitable biomarker candidate. In our
30
31 study, isoxanthohumol was only identified in hops extracts and beer samples (level 1), but not in urine
32
33 and plasma (data not shown). This may be related to the low concentration of isoxanthohumol in urine
34
35 and plasma; prenylated hops phenol glucuronide conjugates accounted for only 2% of the dose^{47, 48}.
36
37
38 The gut microbial biotransformation of xanthohumol to prenylnaringenin in humans has been shown to
39
40 vary from 0-100% between individuals⁴⁹. This may also explain the relatively low sensitivity observed
41
42 previously for this marker⁴⁶.
43
44
45

46 47 **Conclusions**

48
49 The concept of aggregated biomarkers proposed here may find widespread use to solve the problems of
50
51 overlapping markers for intakes of many foods and especially for processed foods and whole diets. A
52
53 recent study demonstrated that aggregated biomarkers provide higher sensitivity and specificity for
54
55 intake of sugar sweetened beverages compared to single biomarkers⁵⁰. Further development of this
56
57
58
59
60

1
2
3
4 concept will be to move it from the stage of providing qualitative markers to actually estimating the
5 amount ingested and the time elapsed since ingestion. This should eventually be possible based on the
6
7 different kinetics of the individual metabolites included in the aggregated biomarkers.
8
9

10
11 In conclusion, we were able to segregate metabolites that are increased following beer intake into
12 compounds originating from hops, wort, fermentation, and human metabolism. The majority of beer-
13 specific compounds originate from hops, but many of these are chemically unstable limiting their
14 usefulness as single biomarkers. Many of the suggested biotransformation products of IAAs are novel,
15 yet still need to be fully structurally characterized. We propose that wort and fermentation products
16 may provide signature markers of beer intake in combination with one or more hops-specific marker.
17
18 Therefore, we have shown here that an aggregated biomarker model based on a set of three out of four
19 of these signature biomarkers was able to completely discriminate between samples collected after beer
20 intake in an independent study with high sensitivity and specificity. It still remains to be shown that the
21 aggregated biomarker of beer intake proposed herein is sensitive and specific in an observational
22 setting and whether adjustments may be needed, e.g. adding markers for optional beer components
23 such as reduced IAAs, caramel, wheat, corn, etc.

Figure Legends

Figure 1. SCA score plot of the test drink matrix for both the urine (top) and plasma (bottom) metabolic profiles. An SCA model was applied to the effect matrix obtained from the ANOVA decomposition.

Figure 2. Iso-cohumulone excretion profiles in urine (A) plasma (B) and test beer levels (C).

Figure 3. Urinary excretion profiles of pGlu-pro (A), NMT sulfate (B) and 2-ethyl malate (C).

Figure 4 (A) PLSDA scores plot of the first component. The calibration model is developed using the measurements of four metabolites for samples from the meal study 1 (filled circles) and the model is tested with samples from meal study 2 (open circles). C and B refer to control samples and 24 h pooled samples from the meal the meal study 1, respectively. Ctest and Btest refer to the samples before and collected up to 12 h following beer intake from meal study 2 (B) ROC curve describing the performance of the PLSDA model in terms of predicting beer intake for calibration (CV) and test set (TV) samples, respectively.
