Abstract

The aim of this study is to develop compact yet comprehensive multi-component diesel surrogate fuel models for computational fluid dynamics (CFD) spray combustion modelling studies. The fuel constituent reduced mechanisms including n-hexadecane (HXN), 2,2,4,4,6,8,8-heptamethylnonane (HMN), cyclohexane (CHX) and toluene developed in Part I are applied in this work. They are combined to produce two different versions of multi-component diesel surrogate models in the form of MCDS1 (HXN + HMN) and MCDS2 (HXN + HMN + toluene + CHX). The integrated mechanisms are then comprehensively validated in zero-dimensional chemical kinetic simulations under a wide range of shock tube and jet stirred reactor conditions. Subsequently, the fidelity of the surrogate models is further evaluated in two-dimensional CFD spray combustion simulations. Simulation results show that ignition delay (ID) prediction corresponds well to the change of fuel constituent mass fraction which is calculated to match the cetane number (CN). In addition, comparisons of the simulation results to the experimental data of #2 diesel fuel (D2) in a constant volume
combustion chamber show that IDs and lift-off lengths are reasonably well replicated by the models. The MCDS2 model is also found to perform better in the soot formation prediction in D2 fuel combustion as the model contains aromatic and cyclo-alkane components which provide an additional pathway to the formation of rich species such as C\(_2\)H\(_2\) and C\(_6\)H\(_6\). Implementation of MCDS2 predicts an increase of maximum local soot volume fraction by a factor of 2.1 when the ambient temperature increases from 900K to 1000K, while the prediction by MCDS1 is lower at 1.6. This trend qualitatively agrees with the experimental observation. This work demonstrates that MCDS1 serves as a potential surrogate fuel model for diesel fuels with CN values ranging from 15 to 100. It also shows that MCDS2 is a more appropriate surrogate model for fuels with aromatics and cyclo-paraffinic contents, particularly when soot calculation is of main interest.

Keywords: multi-component diesel surrogate, CFD simulations, spray combustion, chemical kinetic mechanism, soot formation.

1. Introduction

In multi-dimensional computational fluid dynamics (CFD) modelling studies [1–6], n-heptane has been widely utilised as a single-component diesel surrogate fuel model owing to its cetane number (CN) of 55, which is comparable to those of the actual diesel fuels which range between 40 to 56 [7]. Nonetheless, actual diesel fuels generally consist of long carbon chain structure with 10 to 25 carbon atoms [7]. Fuels with long-chain n-alkanes exhibit higher reactivity at low temperatures as compared to those with short carbon chains. This is due to the higher ratio of secondary to primary hydrogen atoms which then increases the H-atom abstraction rate during the initiation phase of the oxidation of alkanes [8]. As a consequence, the combustion of long-chain hydrocarbons particularly n-hexadecane (HXN) [9] has become the centre of attention in many current research works [10–13]. HXN is the
primary reference fuel and it has a CN of 100. Surrogate fuel models with different CN values can hence be produced when HXN is blended with other fuels such as 1-methylnaphthalene with a CN of 0 and 2,2,4,4,6,8,8-heptamethylnonane (HMN) with a CN of 15. Therefore, HXN has been identified as a promising component for diesel fuel surrogate model in recent works [12–14]. Nonetheless, it is evident that the Hydrogen/Carbon Molar Ratio (H/C) of HXN is different from that of the actual diesel fuels, on top of the difference in CN. H/C ratio is a key property in simulation studies in order to replicate combustion properties such as heat of reaction, local air/fuel stoichiometric location, flame temperature and flame speed [15]. It is important to note that similar restriction is expected to hold for any other single-component diesel surrogate fuels [16,17].

Apart from that, the Polycyclic Aromatic Hydrocarbons (PAH) formation in diesel fuel combustion is not well described by a single-component diesel surrogate fuel model [7]. In the experiment carried out by Kook and Pickett [18], soot formation of a surrogate fuel comprising 23% m-xylene and 77% n-dodecane (by volume) was studied and the sooting tendency was subsequently compared to a conventional jet fuel under diesel-engine like conditions. Their planar laser induced incandescence (PLII) measurement revealed that the soot level produced by the n-dodecane/m-xylene surrogate fuel is higher than that of the conventional jet fuel. For the combustion of fuels that do not contain aromatic compounds, the maximum local soot volume fraction (SVF) increases by a factor of approximately two when the ambient temperature rises from 900K to 1000K. On the other hand, the maximum SVF increases by a factor of at least five for the combustion of fuels which consist of aromatic volume of 23% to 27%. This corresponds with the reported experimental studies [19–22] where the sooting tendency of a single-component surrogate model is comparatively less significant than an alkane/aromatic mixture. Single component diesel surrogate models
which do not contain PAH chemistry in its original fuel composition are hence debatable since actual diesel fuels contain 20% to 30% of aromatic compounds [23].

Recognizing the limitation of single-component diesel surrogate fuel models, development of surrogate models with matching fuel compositions as the actual diesel fuels is necessary. Consequently, multi-component diesel surrogate models with blends of various fuel components have been proposed [7,24–30]. The details of the surrogate mechanisms, together with their respective constitutional components are provided in Table 1. In the earlier years, the number of components in a surrogate model was limited owing to the complexity in solving the stiff ordinary differential equations and the associated high computational cost. Besides, huge quantity of work was required to develop the database and mechanistic understanding of the surrogate components for diesel fuels [7]. Fuel blends which are commonly employed in numerical simulations of diesel combustion are Integrated Diesel European Action (IDEA) mechanism [27,28,31], Primary Reference Fuels (PRF) mechanism [32–35] and Diesel Oil Surrogate (DOS) mechanism [36]. With rapid advancement in chemical kinetics as well as computing power, surrogate models with greater number of fuel components are established such as PRF+1 mechanism [24] and Toluene Reference Fuel/PAH (TRF-PAH) mechanism [25]. Nonetheless, PRF, PRF+1 and TRF-PAH surrogate models are predominantly developed for homogeneous charge compression ignition (HCCI) applications. In these chemical models, n-heptane is mainly employed to represent the n-alkane component. Although the component mass fraction in these fuel blends can be adjusted to generate diesel surrogate models with different CN, the maximum boundary of the CN range is constrained by the CN of n-heptane. Thus, they are not suitable to be used as surrogate models for fuels with higher CN such as a paraffinic diesel reference fuel blend [37] with a CN of 80. More recently, POLIMI_Diesel_201 mechanism has been developed by Ranzi et al. [38] which consists of toluene, xylene, methylnaphthalene and n-alkanes up to
HXN. The mechanism was well validated in chemical kinetic simulations through comparison of the ignition delay (ID) predictions with experimental measurements of a binary diesel surrogate mixture under auto-ignition condition [39]. On the other hand, Chang et al. [29] have also formulated a diesel surrogate fuel model comprising toluene, n-decane, iso-octane and methylcyclohexane. These hydrocarbons are selected to represent the aromatics, straight-, branched- and cyclo-alkane components in the actual diesel fuels, respectively. The integrated mechanism was comprehensively validated against the experimental data for each fuel constituent and blends, as well as for practical diesel fuel under wide-ranging operating conditions. However, the performance of these two surrogate models [29,38] is yet to be tested in multi-dimensional CFD modelling studies.

Set against this background, this study aims to develop appropriate multi-component diesel surrogate models which account for both diesel fuel ignition and combustion across wider CN range of actual diesel fuels. The reduced models of surrogate components for diesel fuels including HXN, HMN, cyclohexane (CHX) and toluene generated in Part I are applied here. Two combinations of multi-component diesel surrogate models with different fuel compositions and components are developed and first validated in zero-dimensional (0-D) chemical kinetic simulations. The first model consists of straight- and branched-alkanes while the second consists of aromatics, straight-, branched- and cyclo-alkanes. The fidelity of the multi-component models is further appraised through the comparisons made between measurements of a constant volume combustion chamber and the numerical results of two-dimensional (2-D) CFD spray combustion simulations. The study also examines the performance of the surrogate models in predicting soot formation with and without the inclusion of aromatics/cyclo-alkane components.

2. Development and Validations of Multi-Component Diesel Surrogate Fuel Models
In this section, a sequential procedure is applied to formulate the multi-component diesel surrogate models, as illustrated in Fig. 1. The procedure is similar to the model construction scheme of Slavinskaya et al. [40]. Here, a ‘reduced-then-combined’ model construction strategy is employed where the reduced models for each of the fuel components are first derived from the respective detailed models and are subsequently combined together to generate the multi-component diesel surrogate models. As such, the reduced models for each of the components are constructed and may be used for other applications. This strategy also limits errors and complications generated from reducing the combined, detailed surrogate models with more than 3,500 species.

The target applications of this work focus on chemical composition match as well as mimicking the combustion and soot precursor formation behaviours of real diesel fuels such as #2 diesel fuel (D2). In this work, the reduced mechanism of HXN is designated as the base mechanism as it is the most abundant and largest hydrocarbon among the fuel constituents. Subsequently, the reduced mechanisms for other surrogate fuel components are added to the base mechanism to generate two combinations of multi-component diesel surrogate models:

(a) Multi-Component Diesel Surrogate No. 1 (MCDS1): HXN + HMN;

(b) Multi-Component Diesel Surrogate No. 2 (MCDS2): HXN + HMN + toluene + CHX.

The reduced mechanisms of HXN, HMN and CHX generated in Part I are employed. It is noted that the base chemistries of the fuel constituents are essentially similar as the reactions mechanisms are constructed based on the hierarchical nature of hydrocarbon–oxygen systems [9,41,42] in order to ensure that the results may not be affected when the based model is replaced by different models. The approach is similar to the model construction of the detailed mechanisms of n-heptane and iso-octane by Curran et al. [43,44].

The CN of MCDS1 is calculated using Equation (1):
\[ CN \text{ of mixture} = [F_{HXN} + 0.15F_{HMN}] \times 100 \] (1)

\( F_{HXN} \) is the mass fraction of HXN and \( F_{HMN} \) is the mass fraction of HMN. The CN and compositions of MCDS1 are determined based on those of Diesel Primary Reference Fuel (DPRF58) \([45]\). DPRF58 is a fuel mixture of 42% HXN and 58% HMN by mass, corresponding to a CN of 50.7. It was found to yield the same ID timings as the D2 fuel experimentally \([46,47]\). However, Equation (1) is not applicable for fuel model which considers other components. The compositions of MCDS2 are hence determined based on those of the D2 fuel. The composition of toluene is fixed at 28\% which is close to the aromatic composition of D2 provided in the study by Kook and Pickett \([48]\) and it is also approximately the average value of the aromatic composition of typical North American diesel fuels \([7]\). Subsequently, mass fractions of the remaining fuel components such as HXN, HMN and CHX are iterated to match the IDs of D2. The properties of D2, MCDS1 and MCDS2 surrogate models as well as size of the surrogate models are presented in Table 2.

Upon the construction of the multi-component diesel surrogate models, the relative contribution of each reaction pathway to the net production rate of each species has altered as compared with that of the respective single-component model. The reaction pathways of each fuel species in the multi-component diesel surrogate mechanisms are hence reassessed using reaction pathway analysis. It is observed that there are certain species which can be removed from the mechanisms owing to their insignificant effect on the predictions of fuel oxidation process upon integration. One of the examples of the eliminated species is the alkyl radical of HMN, namely HMN-R1. It is formed mainly through H-atom abstraction and alkyl radical decomposition from the fuel species. During the reduction of the detailed HMN mechanism, two isomers of HMN are retained during chain-branching process such as HMN-R8 and HMN-R1. However, when HMN is combined with other fuel components in the MCDS1 and MCDS2 surrogate mechanisms, influence of HMN-R1 onto the formation of intermediate
species during chain branching process has become less significant. Therefore, HMN-R1, together with its corresponding reactions and connected species are removed from the mechanism. The species and reaction elimination process is performed in the following steps:

(i) Reaction path analysis is carried out for all test conditions. Here, the species for H2/CO and small hydrocarbon oxidations are not taken into consideration as these pools of species are shared by the fuel constituents in the integrated models. The normalised temperature A-factor sensitivities (as defined in Part I) for all reactions involving the potential eliminable species are calculated. If the sensitivity coefficient values for all the corresponding reactions are lower than the user-specified threshold value (i.e. 0.05) across all the test conditions, the species is then selected for the subsequent elimination procedure.

(ii) The model accuracy in ID and species profile predictions is selected as the criterion for the species elimination procedure upon model integration. Hence, the 0-D simulations across all the test conditions are repeated whenever a species is eliminated from the mechanism along with its corresponding elementary reactions so that the model predictions are not affected. The maximum relative error tolerance between the model predictions before and after elimination procedure is retained to within 5%. Sizes of the final, reduced multi-component diesel surrogate models are provided in Table 2.

Subsequently, mechanism validations in 0-D simulations are performed using the MCDS1 and MCDS2 diesel surrogate models for:

i) ID timing of each diesel fuel component (Fig. A1 in Appendix A);

ii) species concentration profiles of each diesel fuel component under auto-ignition (Fig. A2 in Appendix A) and JSR conditions (Fig. A3 in Appendix A);

iii) species concentration profiles of each diesel fuel component in a JSR (Fig. 2); and

iv) ID timing of DPRF58 [45] and n-dodecane (n-C12H26) [9]. (Fig. 3)
The test conditions applied here are described in part I. It is noteworthy that the computational results generated by both multi-component diesel models are plotted together with those predicted by each fuel constituent model. The purpose here is to demonstrate that the performance in predicting the ID timings and species concentrations retains after mechanism integration is carried out.

In Fig. A1, the computed IDs for HXN and HMN oxidations using MCDS1 and MCDS2 surrogate models are similar as the elementary reactions for HXN and HMN in these two mechanisms are the same. Comparison of ID timings and species profiles with those of CHX detailed mechanism is only performed using MCDS2 as MCDS1 does not contain elementary reactions for CHX. It is observed that the predicted ID timings for each surrogate model agree reasonably well with those of the surrogate components. In addition, trend of the species concentration profiles for both auto-ignition and JSR conditions is retained using both the multi-component surrogate models in comparison with those of each individual diesel fuel component, as shown in Fig. A2 and Fig. A3, respectively. The results for MCDS1 are comparable with those of MCDS2 with only about ±5% deviations. Apart from that, the species concentration profiles in a JSR for each surrogate component are reproduced using the MCDS2 surrogate model. This is demonstrated in Fig. 2. The deviations in the species concentration predictions between the multi-component surrogate models and the individual detailed models for each fuel constituents can be attributed to the influence of kinetic reactions of other fuel components upon model integration. Despite the apparent difference in the absolute values, the relative trends of the species profiles computed by the detailed models are reasonably reproduced by the multi-component surrogate models.

Comparisons of the ID timing predictions between the surrogate models and DPRF58 are shown in Fig. 3(a). Agreement is achieved between the multi-component surrogate and DPRF58 mechanisms in ID predictions throughout the test conditions. Largest deviation is
observed for initial temperature of 850K and $\Phi$ of 1, which is recorded at 33%. The maximum deviations between the computations by the detailed and reduced models are successfully maintained to within an error tolerance of 40%, which is reasonable for large-scale mechanism reduction [51–54]. Apart from that, it is found that MCDS2 with compositions of $F_{\text{HXN}}:F_{\text{HMN}}:F_{\text{C7H8}}:F_{\text{CHX}}$ set to 0.42:0.20:0.28:0.10 yields similar ID timing predictions as DPRF58. In other words, its ignition behaviour is compatible with that of D2. Moreover, the multi-component diesel surrogate mechanisms are further validated in closed homogeneous batch reactor simulations by varying their CN. ID timing predictions are compared in Fig. 3(b) with respect to the detailed n-dodecane mechanism (CN of 87). Composition of $F_{\text{HXN}}:F_{\text{HMN}}$ is set to 0.85:0.15 for MCDS1, corresponding to a CN of 87.25. On the other hand, the fuel composition for MCDS2 is fixed at 0.85:0.15:0:0 for $F_{\text{HXN}}:F_{\text{HMN}}:F_{\text{C7H8}}:F_{\text{CHX}}$. It is observed that the projected ID timings are well replicated using both MCDS1 and MCDS2 diesel surrogate models.

Upon the model validations under a series of different test conditions in the 0-D kinetic simulations, the proposed MCDS1 and MCDS2 surrogate models are coupled with CFD models in the next section to simulate spray combustion and soot formation under diesel-engine like conditions.

### 3. 2-D Spray Combustion Simulations

In this section, 2-D multi-dimensional CFD simulations are carried out to simulate spray combustion and soot formation processes using both the multi-component diesel surrogate fuel models. The spray combustion solver in OpenFOAM-2.0.x is used and a multistep soot model is integrated into the solver [55]. The numerical setups for the reacting diesel fuel sprays are described in Table 3(a). Further description of the numerical setups can be found in the former work [12,13]. In this work, the physical properties of the aromatic compounds...
are represented by those of toluene. On the other hand, the physical properties of the alkanes are represented by the physical properties of n-tetradecane as its physical properties are close to those of real diesel fuels. Thus, the influence of fuel physical properties is isolated and the effect of the chemical kinetics of reaction models can be studied.

Based on the sensitivity study shown in [56], the spatial and temporal evolutions of fourth aromatic ring PAH, pyrene, are similar to those of smaller PAHs or C2H2 when the flame temperature is relatively high (typically under no or low EGR conditions). Hence, implementation of C2H2 as soot precursor is usually a good compromise between results accuracy and simplicity when the PAH chemistry is absent [4,57–59]. C2H2 is selected as the soot precursor in the numerical simulations using the MCDS1 surrogate model as this mechanism does not contain PAH mechanism. On the other hand, C6H6 is present in the MCDS2 surrogate model when CHX mechanism is integrated into the multi-component mechanism during the model development stage. With the presence of the PAH chemistry in the surrogate model, C6H6 is therefore designated as the soot precursor species in the respective modelling studies. In order to simulate the mass addition on soot particle surface, C2H2 is consistently used as the soot surface growth species when MCDS1 and MCDS2 are applied. On the other hand, OH and O2 are set as the soot oxidant species for the calculation of soot mass destruction.

In this section, the numerical simulations are separated into two parts. First and foremost, MCDS1 is applied in a sensitivity test to examine its reactivity towards variation in CN. Mass fractions of HXN and HMN as well as the corresponding CN are shown in Table 3(b). It is then followed by the validation of both MCDS1 and MCDS2 using the measurements of D2 fuel [18,48] from constant volume combustion chamber experiments. Mass fraction of each component is varied to mimic the actual fuel properties, which are detailed in Table 2. Operating conditions used for this validation exercise are demonstrated in Table 3(c).
Measurements are available for reacting spray test cases at 15% \( \text{O}_2 \) mole fraction. This condition represents a reactive environment of air diluted with exhaust gas recirculation. The ambient temperature varies from 900K to 1000K while the ambient density is fixed at 22.8kg/m\(^3\). The computed ID, lift-off length (LOL) and SVF are compared to the experimental data. For the simulation results, ID is defined as the maximum \( \Delta T/\Delta t \) gradient of the temperature profile. On the other hand, LOL is defined as the distance from the injector to the closest layer where OH mass fraction reaches 2% of its maximum value in the domain. These definitions correspond with those recommended by Engine Combustion Network [50].

### 3.1 Sensitivity Test of the MCDS1 Surrogate Model on CN Variations

The effects of variation in CN on LOL and ID predictions are demonstrated in Fig. 4(a). As the CN increases, it is expected that the ID becomes shorter. Thus, the ignition occurs at a location closer to the injection tip and the associated flame lift-off is hence shorter. The trend is replicated by the model. Based on the results shown in Fig. 4(a), it is observed that the kinetics of MCDS1 surrogate model is sensitive to changes in CN ranging from 15 to 100. MCDS1 serves as a promising surrogate model for diesel fuels with various CN.

In the next section, the MCDS1 model is further validated using the D2 fuel data. Its performance is also compared against that of the counterpart MCDS2 which considers CHX and toluene reactions.

### 3.2 Validation using D2 experimental data

The predicted IDs and LOLs by MCDS1 and MCDS2 surrogate models for D2 fuel combustion at ambient temperatures of 900K and 1000K are demonstrated in Fig. 4(b). It is observed that the predictions follow the overall trend where the calculated ID and LOL decrease with increasing ambient temperature. The maximum deviations in ID and LOL
predictions with respect to the experimental measurements retain within 15.4% and 23%, respectively. The IDs calculated using MCDS1 agree well with the measurements in both cases but shorter LOLs are produced. On the other hand, the predicted IDs and LOLs are slightly longer in both cases when MCDS2 is applied. This can be attributed to the inclusion of toluene which is difficult to ignite. As it is considered in the initial composition of the MCDS2 model, the resulting ID becomes longer. The flame hence stabilises at a location further downstream from the injection tip, yielding a longer LOL. It is noted that the deviations between the experimental and computed LOLs using MCDS2 are less pronounced, where deviations of 3.5mm and 2.5mm are recorded for ambient temperatures of 900K and 1000K, respectively. It is worth mentioning that the deviations between the measured and computed LOLs can also be attributed to the absence of turbulence – chemistry interaction (TCI) in the numerical computations. Inclusion of TCI effects has been shown important to improve the prediction of the OH distributions and hence the development of flame lift-off [60–62].

In addition, the SVF predictions of D2 fuel using MCDS1 and MCDS2 are demonstrated in Fig. 5(a). The predictions are compared with the experimental soot clouds [18] obtained at quasi-steady state (4ms after start of injection) for ambient temperatures of 900K and 1000K. These experimental soot images are obtained from the PLII measurement which provides two-dimensional information of SVF distributions for D2 fuel. The red dashed lines on the images indicate the flame LOLs and only qualitative information of soot distribution in the fuel jets is provided based on the images obtained from the experiment. In Fig. 5(a), it is observed that the soot length predicted by MCDS2 is similar to that of the experimental measurements for D2 fuel combustion at ambient temperatures of 900K and 1000K. In contrast, the simulated soot clouds appear to be larger than the soot clouds observed in the experiments for both cases when MCDS1 is employed. In comparison to the predictions of
MCDS2, the soot clouds predicted by MCDS1 are formed at further upstream locations closer to the injection tip. This can be attributed to the associated shorter LOLs. Subsequently, quantitative SVF predictions along spray axis at quasi-steady state for D2 fuel combustion are demonstrated in Fig. 5(b). Results in Fig. 5(b) shows that the local SVF values produced by MCDS1 and MCDS2 are different. MCDS1 estimates maximum local SVF values of 15ppm and 24ppm for the 900K and 1000K test cases, respectively. On the other hand, the maximum local SVF values predicted by MCDS2 for the 900K and 1000K test cases are 5.8ppm and 12.2ppm, respectively. It is observed that the local SVF given by MCDS1 is consistently higher than that of MCDS2. This can be attributed to several reasons. First of all, the LOLs predicted by MCDS1 are shorter. The associated amount of air entrained into the fuel rich core region is lesser. Besides this, MCDS1 utilises C$_2$H$_2$ as soot precursor while MCDS2 uses C$_6$H$_6$. The mass concentration of C$_2$H$_2$ is commonly higher than that of PAH, leading to higher level of soot inception rate and hence soot mass gained. Lastly, as compared to MCDS1, the amount of branched-alkane (i.e. HMN) used in the initial fuel composition of the MCDS2 model is lower. As a consequence, the production rate of C$_2$H$_2$ drops and the soot mass gained through the soot surface growth process decreases correspondingly, yielding lower SVF values.

The next parameter used to evaluate the performance of the multi-component surrogate models is the soot formation behaviour at different ambient temperatures. The results indicates that the predicted maximum local SVF increases by a factor of 1.6 as the ambient temperature is raised from 900K to 1000K when MCDS1 is applied. The use of MCDS2 increases the maximum local SVF by a factor of 2.1. The ratio of increment in maximum SVF from ambient temperature of 900K to 1000K is henceforth represented by ratio$_{SVF}$ for brevity. Based on the measurement presented by Kook and Pickett [18], the experimental ratio$_{SVF}$ is more than three for D2 fuel combustion. The use of MCDS2 is found to improve
the overall simulated ratio\textsubscript{SVF}. This can be attributed to the inclusion of aromatic and cyclo-
alkane components in the initial fuel composition in MCDS2. At different ambient
temperatures, the production of C\textsubscript{2}H\textsubscript{2} is different when the aromatic and cyclo-alkane
components are considered and omitted. This is further elaborated in the subsequent section.

Numerical analysis of C\textsubscript{2}H\textsubscript{2} and C\textsubscript{6}H\textsubscript{6} formations is performed at times when temperature
rises by 100K, 200K, 400K, 800K and 1000K from the initial ambient temperatures. The
results are demonstrated in Fig. 6 and the temperature tolerance for this comparison study is
\pm 20K. Besides these, C\textsubscript{2}H\textsubscript{2} and C\textsubscript{6}H\textsubscript{6} formations at quasi-steady state are also provided, in
which the computed results are obtained at 4ms after the time of injection to ensure that the
formation of the selected species in all test cases reaches a quasi-steady state. The
observations obtained from the numerical analysis are discussed below:

(i) Results in Fig. 6(a) depict that the amount of C\textsubscript{2}H\textsubscript{2} produced at the temperature rise of
100K from the initial ambient temperatures of 900K and 1000K is lower than C\textsubscript{6}H\textsubscript{6} when
both MCDS1 and MCDS2 are applied. C\textsubscript{6}H\textsubscript{6} is mainly produced through the breakdowns
of cyclo-paraffin ring as well as toluene via R1 to R4.

\[
\text{CYCHEXENE} + \text{OH} \leftrightarrow \text{CYHX1N3J} + \text{H}_2\text{O} \quad \text{(R1)}
\]
\[
\text{CYHX13ENE} + \text{H} \leftrightarrow \text{CYHX1N3J} \quad \text{(R2)}
\]
\[
\text{CYHX13ENE} \leftrightarrow \text{C}_6\text{H}_6 + \text{H}_2 \quad \text{(R3)}
\]
\[
\text{C}_6\text{H}_5\text{CH}_3 \leftrightarrow \text{C}_6\text{H}_6 + \text{CH}_3 \quad \text{(R4)}
\]

(ii) At temperature interval of 200K from the initial ambient temperatures, it is observed that
the maximum values of C\textsubscript{2}H\textsubscript{2} calculated using MCDS2 are approximately two-fold and
five-fold greater than those predicted by MCDS1 in the 900K and 1000K cases,
respectively. This is depicted in Fig. 6(b). The apparent differences in the predicted C\textsubscript{2}H\textsubscript{2}
levels can be attributed to the significant amount of C\textsubscript{6}H\textsubscript{6} produced by MCDS2, which
subsequently leads to higher production rate of C$_2$H$_2$ as compared to that of MCDS1.

The key formation pathways to C$_2$H$_2$ from C$_6$H$_6$ are described by reactions R5 to R7.

\[ \text{C}_6\text{H}_6 \rightleftharpoons 2\text{C}_3\text{H}_3 \]  \hspace{1cm} (R5)

\[ \text{C}_3\text{H}_3 + \text{H} \rightleftharpoons \text{C}_3\text{H}_2 + \text{H}_2 \]  \hspace{1cm} (R6)

\[ \text{C}_3\text{H}_2 + \text{OH} \rightleftharpoons \text{C}_2\text{H}_2 + \text{HCO} \]  \hspace{1cm} (R7)

(iii) In Fig. 6(c), it is observed that the peak mass fractions of C$_2$H$_2$ in the 1000K cases are consistently higher than those in the 900K cases when the initial ambient temperatures increase by 400K, disregards the use of MCDS1 and MCDS2. This is due to the higher production rate of C$_2$H$_2$ from the dissociation of C$_6$H$_6$ by R5 to R7 using MCDS2 as well as the consumption of C$_2$H$_4$ using both MCDS1 and MCDS2 in the 1000K cases. The formation of C$_2$H$_2$ is significantly dependent on C$_2$H$_4$ and the main formation pathways from C$_2$H$_4$ to C$_2$H$_2$ are described by reactions R8 to R10.

\[ \text{C}_2\text{H}_4 + \text{M} \rightleftharpoons \text{C}_2\text{H}_2 + \text{H}_2 + \text{M} \]  \hspace{1cm} (R8)

\[ \text{C}_2\text{H}_4 + \text{OH} \rightleftharpoons \text{C}_2\text{H}_3 + \text{H}_2\text{O} \]  \hspace{1cm} (R9)

(iv) At temperature interval of 800K from the initial ambient temperatures, the associated mass fractions of C$_2$H$_2$ predicted by MCDS1 start to grow significantly and the peak values match with those produced by MCDS2, as demonstrated in Fig. 6(d). As discussed in the previous section, MCDS1 contains higher amount of branched-alkane in the initial fuel composition. As a result, the production rate of C$_2$H$_2$ becomes higher than that of MCDS2 which eventually results in the current observation.

(v) Same observation as of Fig. 6(d) persists until approaching ignition points.

(vi) The associated mass fractions of C$_2$H$_2$ continue to rise and eventually those predicted by MCDS1 become higher for both 900K and 1000K cases upon reaching a quasi-steady...
state, as illustrated in Fig. 6(f). This corresponds well with the earlier findings in Fig. 5(b), in which SVF predictions by MCDS2 are lower for both 900K and 1000K cases. The current results suggest that the MCDS1 model is useful for the soot formation simulations where the effect of aromatic chemistry plays a less significant role. For instance, Vishwanathan and Reitz [63] reasonably captured the variation of SVF with respect to the change of injection pressure and injector diameter using a single-component surrogate model, namely n-heptane, showing that the presence of aromatic compounds has less pronounced impact on such application. On the other hand, this work demonstrates that the overall soot formation predictions have been improved by considering cyclo-alkane and aromatic compounds. The revised counterpart, MCDS2, is found to predict a higher ratio of SVF when the ambient temperature varies. Yet, the computed ratio is under-predicted as compared to that of the experiment measurement where ratio > 3 is recorded. Further improvement is necessary on the coupled MCDS2-soot model to simulate the complex soot formation phenomenon.

The ambient pressure is increased to retain the ambient density of 22.8kg/m\(^3\) as the ambient temperature varies between 900K and 1000K in the current test cases. However, the conventional multistep soot model does not capture pressure effects of soot formation [56]. The current soot model assumes that soot particles grow primarily by the addition of gaseous C\(_2\)H\(_2\). The use of a pressure dependent surface growth model constant is expected to improve ratio. Alternatively, the inclusion of PAH condensation effects on soot formation under such high pressure, high temperature environment may aid to improve the prediction as well. Bisetti et al. [64] who implemented Hybrid Method of Moments in their Direct Numerical Simulation of soot formation in the n-heptane/air turbulent non-premixed flame revealed that PAH condensation is significant to the soot mass generation.
It is noteworthy that NOx submodel was not included in the multi-component diesel surrogate fuel models. Despite of this, these fuel models are expected to produce reasonable predictions for thermal NOx, which is the major portion of NOx emissions in conventional diesel engines. Thermal NOx formation rate is highly dependent on temperature [65], hence reasonable predictions of the temperature is the pre-requisite for the associated calculation.

In the current numerical simulations, the maximum local temperatures calculated by the integrated fuel models are between 2300K and 2400K. These predictions are consistent with those obtained in the study of Pickett et al. [66] for 15% ambient oxygen. Apart from these, it is noteworthy that the accurate predictions of OH concentrations are essential for simulating thermal NOx formation. Based on the kinetic studies in the 0-D simulations (as shown in Fig. A2 and A3 in Appendix A), it is observed that the OH mole fractions predicted by the integrated models correspond reasonably well with the computations of the detailed models. However, it should also be highlighted that the computation of thermal NOx emissions also depends on the associated Arrhenius rate constants [67]. Hence, the surrogate models can be useful for thermal NOx simulations only when they are integrated with the extended Zeldovich reaction rates which are validated for engine applications.

4. Conclusions

In this study, two multi-component diesel surrogate models namely MCDS1 and MCDS2 with different fuel compositions and components have been introduced. MCDS1 model consists of straight- (HXN) and branched- (HMN) alkanes while MCDS2 consists of aromatic hydrocarbon (toluene), straight- (HXN), branched- (HMN) and cyclo- (CHX) alkanes. Surrogate fuel models with CN values ranging from 15 to 100 can be produced through blending of HXN and HMN. In addition, CHX and toluene are incorporated into MCDS2 model to achieve compositional match and to improve soot formation predictions. The integrated models are comprehensively validated in 0-D chemical kinetic simulations.
under a wide range of shock tube and JSR conditions, by comparing the computations to
those predicted by each detailed and reduced fuel constituent models. It is found that
performance of the surrogate models in ID and species concentration predictions under both
auto-ignition and JSR conditions is maintained after mechanism integration. Apart from
these, the integrated models are also validated against the JSR experimental results for each
diesel fuel constituents. Overall agreement between the computations and measurements is
achieved with maximum deviations of one order of magnitude on the absolute values.
Following that, the fidelity of both multi-component diesel surrogate models is further
assessed in the 2-D spray combustion simulations. Numerical results reveal that MCDS1 is
sensitive to the change of CN. The predicted ID and LOL correspond well with the variation
of CN. Next, ID, LOL and SVF calculated using MCDS1 and MCDS2 are validated against
constant volume combustion chamber experimental data. ID and LOL predictions given by
both surrogate models agree reasonably well with the D2 measurements. Besides, it is
observed that MCDS2 is able to provide better predictions in soot formation events than
MCDS1 due to the inclusion of aromatic and cyclo-alkane components. It is revealed that
ratio$_{\text{SVF}}$ of 1.6 is obtained for D2 fuel combustion when the ambient temperature increases
from 900K to 1000K with the absence of aromatic and cyclo-alkane components. The
simulated ratio$_{\text{SVF}}$ increases to 2.1 when both components are incorporated into the base
mechanism as the inclusion of these two components provides alternative pathways to form
rich species such as C$_2$H$_2$ and C$_6$H$_6$. In this work, the effects of including aromatic and cyclo-
alkane components in the surrogate model on soot formation events are highlighted. It is
demonstrated that MCDS2 is a potential surrogate model for D2 fuel. Nonetheless, additional
work is required to improve the coupled MCDS2-soot model in simulating the complex soot
formation phenomenon.
