Keywords: optomagnetic detection, magnetic nanoparticles, injection molding, rolling circle amplification

We present an injection molded polypropylene (PP) chip with passive liquid handling designed for the automation of an isothermal rolling circle amplification (RCA) assay. Furthermore, we demonstrate on-chip optomagnetic (OM) readout of the synthesized rolling circle products (RCPs) based on their size. For this, we use a type-B influenza virus synthetic target and optimize the RCA temperature for achieving enhanced RCP size. The work shows the feasibility of integration of the OM readout with a multichamber injection-molded chip with temperature control and presents the results of a pilot study towards a complete on-chip assay.

In RCA, padlock probes hybridize to the matching target and form circles upon ligation. These circles act as the template for linear isothermal amplification using phi29 polymerase. A long RCP, with repeats of the sequence complementary to the circle, is formed [1]. The efficiency of the amplification, in terms of RCP size, is highly influenced by the reaction temperature.

The polymer chip consists of two 1 mm thick injection moulded parts of PP polymer (PP grade RF366MO) that are ultrasonically welded to each other [2]. The chip layout features three circular chambers (Ø 5 mm) of height $H = 200 \mu m$ with a sequence of phaseguides of height $h = 60 \mu m$ to control and enable filling of each chamber with a different liquid (Fig. 1a) from the inlets. Each chamber is connected to a waste chamber, which is then connected to an outlet. The three chambers enable future integration of the complete assay on the chip, but in this work they are filled with the same liquid.

The automation and measurement setup consists of a motorized stage that shifts the chip position between (1) a heater bed regulated by a Peltier element and (2) a position for transmission OM measurements (λ = 405 nm LED, photodetector, two electromagnets) (Fig. 1b). RCA mixture contains ligated circles hybridized to the biotinylated target and attached to streptavidin magnetic nanoparticles (MNPs), phi29 and other reagents for amplification. After loading the chip with RCA mixture, the inlets and outlets are sealed using tape. The chip is then placed in position (1) at temperature $T$ and RCA is performed for 20 min followed by quick cooling to 25°C. Then, the motor stage shifts the chip to position (2), where the OM spectra are recorded. The entire procedure is automated in LabVIEW, with each cycle (from loading the chip on the setup to the last measurement) lasting around 30 min.

The OM technique relies on measurements of the 2nd harmonic modulation of the light transmitted through a suspension of MNPs vs. frequency of an applied magnetic field. In the resulting OM spectrum $(V_f/V_0)$ a peak is centered at a frequency, which is inversely proportional to the hydrodynamic volume of the MNPs [3]. In this work, we studied the spectra after amplification for 20 min at $T$ ranging from 20 to 44°C to determine the value of $T$ resulting in the most efficient RCA in terms of RCP size (i.e. the largest RCP corresponding to the lowest value of the peak frequency) (Fig. 2). Excessively low temperature (~20°C) results in low enzyme activity while too high temperature (~42°C) deactivates the enzyme. The results show that the largest product was obtained for $T = 38°C$. Future work aims to integrate on-chip RCA and OM readout with sample preparation (extraction and ligation).

Figure 2: OM spectra of suspensions of MNPs with attached targets/RCPs measured at 20°C after 20 min of RCA. The figure shows representative results obtained for $T = 20, 30, 38$ and 44°C. The frequency of the peak is inversely proportional to the hydrodynamic size of the MNPs.
