Abstract—In this paper, an improved power flow model for dual active bridge (DAB) converters with phase-shift modulation is introduced. Based on the analysis and the accordingly derived equations, a power plateau phenomenon, in which the phase shift loses its power-regulating capability, is investigated. Moreover, it is found that this power plateau phenomenon leads to an inversely power flow characteristic in some specific regions compared to the models reported in previous literature. The characteristics of the power plateau and its occurring conditions are derived and analyzed in depth. The calculations, simulations and analyses have been verified by experiments.

Keywords—dual active bridge; phase shift modulation; power flow model; power flow characteristics

I. INTRODUCTION

The utility grid, once passive and static with a limited number of distributed generators, is now more active and dynamic because of integration of distribution energy resources [1]-[2]. Therefore, solutions such as energy storage systems are required to improve grid reliability and stability [3]. Bidirectional dc-dc converters, which can interface energy storage systems to power conversion systems, have gained increasing attention [4]-[7]. Due to its small number of components, symmetrical structure, isolation capability and soft switching properties, the Dual Active Bridge (DAB) converter has become a popular topology for bidirectional dc-dc power conversion [7].

Several analyses have been implemented on the power flow of DAB converters with a Single Phase-Shift Modulation (SPSM) [8]-[12]. In [8], the power flow equation for a single-phase DAB was derived without considering any losses nor dead time between switches in the same leg. In [9], the short-time-scale transient processes in DAB converters with SPSM were discussed. However, no improvements in the power flow equation were made. In [10], an improved power flow equation was derived considering the dead-time effect and power semiconductor voltage drops, but the equation is not suitable for DAB converters using power MOSFETs; moreover the analyzed cases are limited. In [11], the power flow equation was derived considering MOSFET’s ON resistance, and parasitic resistances of the inductor, transformer and PCB traces; however, the dead time effect was somehow neglected. In [12], the power flow equation was derived considering dead times. With those equations, some power flow characteristics were given, including the power plateau phenomenon which will be further investigated in this paper. However, the model in [12] does not consider any losses.

In this paper, an improved power flow model was derived considering both parasitic resistances and dead time effects. Based on the obtained equations, a power plateau phenomenon is investigated in depth. It is found that Due to the power plateau, the power flow characteristic of the DAB is inversely compared to the previous studies at some specific operation points. Therefore, a comprehensive modeling, as well as its corresponding analysis, is essential for design and control of DAB converters. All calculations and analyses match the simulations well. Furthermore, experimental results from a laboratory prototype verify the analysis, characteristics and influences of the power plateau.

II. IMPROVED DAB MODELING AND ANALYSIS

Fig. 1 shows a single-phase DAB converter, where the magnetizing inductance is neglected. \(L_e\) and \(R_e\) represent the inductance and winding resistance of the external inductor; \(L_{ip,s}, R_{ip,s}\) and \(L_{ip,t}, R_{ip,t}\) represent the leakage inductance and the winding resistance of the transformer primary and secondary, respectively; MOSFETs are treated as a constant resistance when they are triggered ON by driving signals, and as a constant voltage drop when conducting reversely without driving signals; \(G_{i-4}\) represent the driving signals; \(V_1\) and \(V_2\) are DC voltage sources; \(V_{d1}\) and \(V_{d2}\) are the forward voltage of body-diodes and the ON resistance of MOSFETs in the bridge connected to \(V_1\); \(V_{al}\) and \(R_{al}\) are those of MOSFETs in the bridge connected to \(V_2\); \(T_d\) is the dead time; \(f_s\) is the switching frequency. Input power \(P_i\) is defined as power sourcing from \(V_1\), and output power \(P_o\) is power sinking into \(V_2\).
Fig. 2. Typical waveforms of the analyzed case.

Fig. 3. Equivalent circuit of the DAB converter.

Here a special operation condition which leads to the power plateau phenomenon is analyzed. The typical waveforms of the DAB converter working in this case are given in Fig. 2, where assume $V_i>V_N V_2$, and commutation processes are neglected. The inductor current changes direction during the dead time of the active bridge connected to $V_2$. The unified phase shift angle is defined as:

$$d = \frac{\beta}{\pi} \quad (1)$$

where $\beta$ is the phase shift angle.

The equivalent circuit of the DAB converter illustrated in Fig. 1, can be derived as shown in Fig. 3.

$L_{ac}$ and $R_{ac}$ are expressed:

$$L_{ac} = L_{ac,p} + N^2 L_{s,p} + L_e \quad (2)$$
$$R_{ac} = R_{ac,p} + N^2 R_{s,p} + R_e \quad (3)$$

Based on Fig. 2, $v_{ac1}$, $N_{ac2}$ and $i_L$ can then be expressed as follows.

$$V_{ac1}(t) = \begin{cases} 
V_1 + 2V_{di}, t \in [t_0, t_1] \\
V_i - 2R_{ac}N_i \cdot i_L(t), t \in (t_1, t_2) \\
V_i - 2R_{ac}N_i \cdot i_L(t), t \in (t_2, t_3) \\
V_i - 2R_{ac}N_i \cdot i_L(t), t \in (t_3, t_4) \\
V_i - 2R_{ac}N_i \cdot i_L(t), t \in [t_4, t_5] 
\end{cases} \quad (4)$$

Moreover, from Fig. 2, the following equations can be obtained:

$$\Delta t_1 = T_a$$
$$\Delta t_2 = \frac{d}{2f_s} - T_d$$
$$t_4 - t_2 = T_d$$
$$i_L(t_1) = 0$$
$$t_5 - t_0 = \frac{1}{2f_s} \quad (7)$$

At the end of half cycle:

$$i_L(t_5) = -i_L(t_6) \quad (8)$$

Based on (8), the following equation can be obtained:

$$\Delta t = \left( -\frac{1}{J_L} \right) \ln \left( \frac{M_1(1 - e^{\omega s\Delta t}) + M_2(1 - e^{-\omega s\Delta t})}{M_1 + M_2 e^{\omega s\Delta t} + M_3 e^{-\omega s\Delta t}} \right) \quad (9)$$

where $J_1$ to $J_5$ and $M_1$ to $M_3$ are given in Table 1.

### Table 1: Expressions for $J_1$ to $J_5$ and $M_1$ to $M_3$

<table>
<thead>
<tr>
<th>$J_1$</th>
<th>$R_{ac} + 2N^2R_{ac}$</th>
<th>$M_1$</th>
<th>$V_1 + 2V_{di} + V_N V_2$</th>
</tr>
</thead>
<tbody>

</table>
With (9), (7) and (4)–(6), $P_w$ and $P_o$ can be calculated as:

\begin{align*}
P_w & = 2V_1f_s \left( \text{Int}_1 + \text{Int}_2 + \text{Int}_3 + \text{Int}_4 + \text{Int}_5 \right) \\
P_o & = 2V_2 \cdot N_f \left( -\text{Int}_1 - \text{Int}_2 - \text{Int}_3 + \text{Int}_4 + \text{Int}_5 \right)
\end{align*}

where $\text{Int}_i$ ($1 \leq i \leq 5$) are the averaged $i_L$ during interval $\Delta t_i$, whose expressions are given as follows:

\begin{align*}
\text{Int}_1 & = M_1 \Delta t_1 + \left[ i_L \left( t_0 \right) - M_1 \right] - \frac{1}{J_1} \left( e^{-J_1 \Delta t_1} - 1 \right) \\
\text{Int}_2 & = M_2 \Delta t_2 + \left[ i_L \left( t_1 \right) - M_2 \right] - \frac{1}{J_2} \left( e^{-J_2 \Delta t_2} - 1 \right) \\
\text{Int}_3 & = M_3 \Delta t_3 + \left[ i_L \left( t_2 \right) - M_3 \right] - \frac{1}{J_3} \left( e^{-J_3 \Delta t_3} - 1 \right) \\
\text{Int}_4 & = M_4 \Delta t_4 + \left[ i_L \left( t_3 \right) - M_4 \right] - \frac{1}{J_4} \left( e^{-J_4 \Delta t_4} - 1 \right) \\
\text{Int}_5 & = M_5 \Delta t_5 + \left[ i_L \left( t_4 \right) - M_5 \right] - \frac{1}{J_5} \left( e^{-J_5 \Delta t_5} - 1 \right)
\end{align*}

\section{III. Characteristics of Power Plateau}

Given $V_1 > NV_2$, the calculations are done to investigate which parameters may have impact on the plateau’s length i.e. phase shift range and where the plateau occurs. The conclusion is that $T_d$ affects the power plateau’s length and location, depending on certain $N$, $L_c$, $V_{dH}$, $V_{dL}$, $R_{onH}$, and $R_{onL}$ since $N$, $L_c$ are mainly determined by the required power, and $V_{dH}$, $V_{dL}$, $R_{onH}$, and $R_{onL}$ are constant once MOSFETs are selected. The influences of $V_2$ are given in section IV. As shown in Fig. 6, with the dead time increasing, the length of the power plateau increases, and its starting points shift to a smaller phase shift angle; however, the ending points keep unchanged.

\section{IV. Effects of Power Plateau on DAB Operation}

During the power plateau, the power flow is unable to be regulated over certain phase shift ranges. Especially in high power applications, where the phase shift angle is usually limited to small values (below $\pi/4$) to suppress reactive power loss, the power plateau takes a large portion of the allowable phase shift angle range and thereby has a negative impact on the converter control.

Moreover, during the plateau, the DAB’s power no longer increases (or decreases) with increasing (or decreasing) lagging
bridge DC voltage $V_2$, and it is named as anti-power phenomenon. Using the parameters listed in Table 2, the calculated output power as a function of $d$ and $V_2$ is plotted in Fig. 7. As shown, at a specific phase shift angle, the output power will increase (or decrease) with decreasing (or increasing) $V_2$ over the specific $V_2$ range.

V. EXPERIMENTAL RESULTS

In order to verify the theoretical analysis, a laboratory prototype with the same parameters given in Table 2 is constructed and tested. Fig. 9 plots the output power as a function of $d$ at different $T_d$. A power plateau can be seen clearly at different $T_d$, therefore, the existence of power plateau and its associated analysis in section III are verified. Fig. 10 and Fig. 11 show the measured waveforms of the transformer port voltages, inductor current and driving signals of the MOSFETs in the $V_2$ active bridge with $d=0.14$ and $T_d=210$ ns. As shown, the inductor current changes its direction during the dead time so that this can verify the analysis given in Fig. 2.

Fig. 7. Calculated output power as a function of $d$ and $V_2$

Fig. 8. Measured output power as a function of $d$ at different $T_d$.

Fig. 10. Measured transformer voltages and inductor current at $d=0.14$ & $T_d=210$ ns.

Fig. 11. Measured driving signals for MOSFETs in lagging bridge at $d=0.14$ and $T_d=210$ ns.

As shown, the inductor current changes its direction during the dead time so that this can verify the analysis given in Fig. 2. Fig. 12 shows that the power flow characteristic is inversed at the specific $V_2$ values. Due to the anti-power phenomenon, additional concerns must be taken in DAB power regulation, especially when on-line calculations [13]-[15] are used.

VI. CONCLUSIONS

In this paper, an improved power flow model for the single-phase DAB converter with phase shift control is derived, considering the conduction loss of MOSFETs and magnetic components and the dead time effects. A special operating condition in which inductor current changes direction during the dead time leads to the so-called power plateau in which the phase shift becomes unable to regulate the power flow. The
power plateau leads to different power flow characteristics compared to the results reported in previous investigations. Thereby, the characteristics of the power plateau are studied, and the impact due to dead time on the power plateau is addressed. All the theoretical analysis, calculations and simulations are verified by experiments. For the cases of $V_1 < NV_2$ and for DAB converters with modulation schemes other than a single phase shift modulation, more investigations to study the DAB converter’s power flow characteristics are needed in the future.
