We discuss recent elastic neutron scattering and scanning tunneling experiments on high-$T_c$ cuprates exposed to an applied magnetic field. Antiferromagnetic vortex cores operating as pinning centers for surrounding stripes is qualitatively consistent with the neutron data provided the stripes have the antiphase modulation. Within a Green’s function formalism we study the low energy electronic structure around the vortices and find that besides the dispersive quantum interference there exists a non-dispersive checkerboard interference pattern consistent with recent scanning tunneling measurements. Thus both experiments can be explained from the physics of a single CuO$_2$ plane.

The competing orders in high-$T_c$ cuprates remain a strong candidate for explaining some of the unusual features of these doped Mott insulators.1–3 The competition between superconducting order and antiferromagnetic order has recently attracted a large amount of both experimental and theoretical attention. In particular, experiments in the mixed state have revealed an interesting coexistence of these order parameters.

Elactic neutron scattering results on La$_2$Sr$_2$CuO$_4$ ($x =$0.10) have shown that the intensity of the incommensurate peaks in the superconducting phase is considerably increased when a large magnetic field is applied perpendicular to the CuO$_2$ planes.6 This enhanced intensity corresponds to a spin when a large magnetic field is applied perpendicular to the CuO$_2$ planes. It has been proposed that besides the dispersive quantum interference there exists a non-dispersive checkerboard interference pattern consistent with recent scanning tunneling measurements. Thus both experiments can be explained from the physics of a single CuO$_2$ plane.

FIG. 1. (a) Real space picture of the spin structure in a checkerboard spin geometry. Black (white) represent spin up (down) while gray reveals the superconducting background. In order to simulate the induced incommensurability each island of antiferromagnetic spins is out of phase with its nearest neighbor. (b) Fourier spectrum of the spin checkerboard structure shown in (a).
in an antiferromagnetic background is the expected situation. However, this might be possible in the highly overdoped regime where the droplets have been inverted to separate magnetic islands. In that case a 45° rotation of the incommensurable peaks would be consistent with a checkerboard spin pattern. In this light it would be very interesting to perform an experiment similar to that of Lake et al. on highly overdoped LSCO. In the case of a connected antiferromagnetic background one would also expect a large weight at ( , )

The physical picture we have in mind is presented in Fig. 2(a). In this real space picture an antiferromagnetic core (center) has pinned a number of surrounding stripes. This pinning effect of SDWs by magnetic vortex cores is a well-known effect from numerical studies.

Both experimentally and theoretically we expect an antiphase modulation of the induced antiferromagnetic ring domains. Indeed as seen in Fig. 2(b), the related diffraction pattern is qualitatively consistent with measurements by Lake et al. of enhanced intensity at the incommensurate points.

Without an applied magnetic field, only disorder can produce a similar pinning effect of the fluctuating stripes. In addition to the creation of more pinning centers when applying a magnetic field, the single site impurities are expected to pin much weaker than the large "impurities" created by the flux lines. This is qualitatively consistent with the measurements by Lake et al. of the temperature dependence of the increased magnetic signal for different magnetic field strengths.

This leads to the question of the electronic structure around extended magnetic perturbations in d-wave superconductors. The many experiments indicating coexistence of d-wave superconductivity and antiferromagnetism mentioned above motivate studies of simple models that enable one to calculate the LDOS in such regions.

The model Hamiltonian defined on a two-dimensional lattice is given by

\[ \hat{H}^0 = - \sum_{\langle n,m \rangle \sigma} t_{nm} \hat{c}_{n\sigma}^{\dagger} \hat{c}_{m\sigma} - \mu \sum_{n\sigma} \hat{n}_{n\sigma}^{\dagger} \hat{n}_{n\sigma} + \sum_{\langle n,m \rangle} (\Delta_n n^\dagger_m n^\dagger_m + \text{H.c.}), \]

where \( c_{n\sigma}^{\dagger} \) creates an electron with spin \( \sigma \) at site \( n \) and \( \mu \) is the chemical potential. The staggering is included in \( M_n \), \( n = (-1)^n M \). The strength of the antiferromagnetic and superconducting coupling is given by \( M \) and \( \Delta \), respectively.

The Hamiltonian \( \hat{H}^0 + \hat{H}^{\text{int}} \) is a simple mean-field lattice model to describe the phenomenology of the coexistence of d-wave superconducting and antiferromagnetic regions. This approach is similar to the starting point of many recent Bogoliubov–de Gennes calculations. The Hamiltonian in Eqs. (1) and (2) can be viewed as the mean-field Hamiltonian of a \( t-U-V \) Hubbard model, where the nearest neighbor attraction \( V \) gives rise to the d-wave superconductivity. In contrast the on-site Coulomb repulsion \( U \) only causes the antiferromagnetism. In this paper we do not diagonalize \( \hat{H} \) in the Bogoliubov–de Gennes scheme since such lattice calculations require unrealistically large gap \( \Delta \) and magnetic field values. Instead we solve the Dyson equation exactly by inverting a large matrix. This approach has previously been utilized extensively to study various short-ranged effects in superconductors, but can also be used for extended perturbations embedded in a \( \hat{G}_0 \) medium. Here \( \hat{G}_0 \) is the Green’s function of the parent medium, in this case a d-wave BCS superconductor. This Green’s function is given by

\[ \hat{G}_0^{-1}(p, \omega) = (\omega + i\delta) \tau_0 - \xi_p \tau_3 - \Delta_p \tau_1, \]

where \( \tau_\alpha \) denote the Pauli matrices in Nambu space and the gap function \( \Delta_p = (\Delta_0/2)[\cos(p_x) - \cos(p_y)] \). The lattice constant \( a_0 \) is set to unity and \( \xi_p = \epsilon_p - \mu \) with

\[ \epsilon_p = -2t[\cos(p_x) + \cos(p_y)] - 4t'[\cos(p_x)\cos(p_y)]. \]

Here \( t'(t') \) refers to the nearest (next-nearest) neighbor hopping integral and \( \mu \) is the chemical potential. We perform the two-dimensional Fourier transform of \( \hat{G}_0(p, \omega) \) numerically by utilizing a real space lattice of \( 1000 \times 1000 \) sites and a quasiparticle energy broadening of \( \delta = 1.0 \) meV.

To simulate the situation around optimal doping of the hole doped cuprates the following parameters are chosen: \( t = 300 \) meV, \( t' = -120 \) meV, \( \Delta_0 = 25 \) meV, and \( \mu = -354 \) meV. When the real space domain affected by \( \hat{H}^{\text{int}} \) involves a finite number of lattice sites \( N \times N \) we can solve the Dyson equation exactly to find the full Greens function. Writing the Dyson equation in terms of real-space (and Nambu) matrices it becomes

\[ \hat{G}(\omega) = \hat{G}^0(\omega)[1 - \hat{H}^{\text{int}}\hat{G}^0(\omega)]^{-1}. \]

The size of the matrix \( [1 - \hat{H}^{\text{int}}\hat{G}^0(\omega)] \) is given by \( (d \times N^2) \times (d \times N^2) \), where \( d \) is an integer equal to the number of components in the Nambu particle-hole spinor and \( N \) denotes the total number of lattice sites affected by the magnetic perturbation. Therefore a real-space lattice with 25 \( \times \) 25 sites affected by perturbations results in a 1250 \( \times \) 1250 matrix to being inverted.
Knowing the full Greens function we obtain the LDOS \( \rho(r, \omega) = -(1/\pi) \text{Im} [G_{11}(r, \omega) + G_{22}(r, \omega)] \), which is proportional to the differential conductance measured in the STM experiments.

We have checked that the above approach reproduces the expected LDOS for unitary nonmagnetic impurities in \( d \)-wave superconductors. 30 Also in this one-impurity case we reproduce the constant-energy LDOS maps recently calculated by Wang and Lee.31,32

Motivated by the qualitative agreement of the spin structure in Fig. 2a with the neutron data, we assume that this represents the induced magnetism around the vortices and calculate the LDOS in this striped environment. To this end we simply restrict the sum in Eq. (2) to include the sites within these magnetic regions. The system is depicted in Fig. 2(a) where the gray background reveals the underlying superconducting state. Again the black (white) squares correspond to the sites affected by the staggered magnetic perturbation.

Figures 3 and 4 show real-space maps of the LDOS summed over a small energy window from −12 to +12 meV in intervals of 1 meV for different strengths of the antiferromagnetic perturbation \( M \). The vortex center is located in the center of the images. Figure 3 (4) is calculated with (without) the antiphase modulation of the adjacent stripes. Thus the spin configuration of Fig. 2(a) corresponds to the images in Fig. 3. The clear difference between the LDOS images of Figs. 3 and 4 reveals that the STM technique can be used to determine this phase relation. It is clearly seen from both Figs. 3 and 4 that the low energy LDOS structure eventually becomes ringshaped as the magnitude of \( M \) increases. In this limit the pinned stripes operate as steep potential walls. Figures 3(a) and 3(b) seem to display the closest resemblance to the experimental data 15 which indicates that the induced magnetism is very weak. In Fig. 5 we show the Fourier transform of several constant energy LDOS images for \( M = 100 \) meV with the antiphase spin modulation included. In these figures the Fourier component \( q = 0 \) is located at the center. The detailed energy dependence of these images is caused by quasiparticle interference effects as pointed out by Wang and Lee31 in the case of a single impurity.

The dispersive features of the images presented in Fig. 5 are dependent on the microscopic parameters and the associated Fermi surface. However, it is also evident that the ring
shaped stripes surrounding the vortex cores give rise to non-dispersive intensity around \( q = (2\pi/4a_0)(\pm 1/4, 0) \) and \( q = (2\pi/a_0)(0, \pm 1/4) \). This in turn leads to the checkerboard pattern in the low energy sums of the LDOS displayed in Figs. 3 and 4 whereas the dispersive features fade away in these summed LDOS images.

We have confirmed this fact by identifying similar non-dispersive features in the LDOS around configurations with different periodicities. For instance, a structure with \( 2a_0 \) charge periodicity leads to a non-dispersive intensity around \( q = (2\pi/a_0)(\pm 1/2, 0) \) and \( q = (2\pi/a_0)(0, \pm 1/2) \).

In the above calculation we have not yet included the Doppler shift from the circulating supercurrents or the gap suppression close to the vortex core. As pointed out by Polkovnikov et al.,\(^{18}\) the former effect is not expected to produce significant changes of the four-period modulations. As for the latter we have checked that a gap suppression only leads to minor quantitative changes in the dispersive part of the LDOS. Finally, Podolsky et al.\(^{34}\) discussed scenarios of weak translational symmetry breaking and found that in order to explain quantitatively the zero-field STM results by Howald et al.\(^{12}\) one needs to include dimerization, the modulation of the electron hopping. This dimerization will also produce quantitative changes, but not alter the qualitative conclusion that pinned stripes produce checkerboard LDOS.

In summary, we have discussed the phenomenology of a simple physical picture of pinned stripes around vortex cores which are forced to be antiferromagnetic by an applied magnetic field. The induction of magnetic striped race tracks around the core is consistent with the neutron diffraction spectra observed on LSCO with a doping level near \( x = 0.10 \). As expected this is only true if the stripes are out of phase with their neighbors in the usual sense. In materials where a checkerboard spin pattern is relevant (possibly Bi2212 or overdoped LSCO), we show that a 45° rotation of the main incommensurable peaks is to be expected. Finally we studied the electronic structure around the vortices and identified a non-dispersive feature in the LDOS arising from the induced static antiferromagnetism. This feature gives rise to the checkerboard LDOS observed experimentally by Hoffman et al.\(^{15}\) Thus both the STM measurements and the enhanced intensity of the incommensurable peaks observed by neutron diffraction can be ascribed to the phenomena of a single CuO\(_2\) plane.

Support by the Danish Natural Science Research Council, Ole Rømer Grant No. 9600548, is acknowledged.
