(Received 1 May 2006; accepted 18 August 2006; published online 27 October 2006)

The magnetic properties of cobalt ferrite–silica nanocomposites with different concentrations (15, 30, and 50 wt %) and sizes (7, 16, and 28 nm) of ferrite particles have been studied by static magnetization measurements and Mössbauer spectroscopy. The results indicate a superparamagnetic behavior of the nanoparticles, with weak interactions slightly increasing with the cobalt ferrite content and with the particle size. From high-field Mössbauer spectra at low temperatures, the cationic distribution and the degree of spin canting have been estimated and both parameters are only slightly dependent on the particle size. The magnetic anisotropy constant increases with decreasing particle size, but in contrast to many other systems, the cobalt ferrite nanoparticles are found to have an anisotropy constant that is smaller than the bulk value. This can be explained by the distribution of the cations. The weak dependence of spin canting degree on particle size indicates that the spin canting is not simply a surface phenomenon but also occurs in the interiors of the particles. © 2006 American Institute of Physics. [DOI: 10.1063/1.2354475]

I. INTRODUCTION

The unique properties of nanoscaled magnetic particles have generated much interest because of their applications in high density data storage, ferrofluid technology, catalysts, color imaging, and magnetically guided drug delivery. An understanding of the relationship between structure, particle size, and magnetic properties is essential in order to design new magnetic materials. In this context, superparamagnetic relaxation is one of the most important effects related to the reduction of particle size. Furthermore, the presence of non-collinear (canted) spin structures is also important in, for example, nanoparticles of ferrimagnetic materials. The presence of canted spins leads to modifications of the magnetic properties and can be quantified by the inversion degree, which is defined as the fraction of divalent ions in the octahedral sites. It has been suggested that the spin canting is a surface phenomenon and therefore it should become increasingly important with decreasing particle size. However, some studies rather indicate that the noncollinear spin structure is a finite size effect which also occurs in the interior of the particles.

Among nanoscaled magnetic materials, nanoparticles of spinel ferrites are of great interest, not only because of their technological applications but also from the point of view of fundamental science. In fact, they are good model systems for studies of the relationship between magnetic behavior and magnetic structure at atomic level. In addition, the structural properties and the rich crystal chemistry of spinels offer excellent opportunities for understanding and fine tuning the magnetic properties.

The ferrite spinel structure \(M^n\text{Fe}_2\text{O}_4\) is based on a closed-packed oxygen lattice, in which tetrahedral (called A sites) and octahedral (called B sites) interstices are occupied by the cations. The physical behavior and, in particular, the magnetic properties depend on the cationic distribution in the A and B sites. Spins with only divalent ions in tetrahedral sites are called normal, while compounds with the divalent ions in the octahedral sites are called inverse. In general, the cationic distribution in octahedral and tetrahedral sites may be quantified by the inversion degree, which is defined as the fraction of divalent ions in the octahedral sites. An important topic in the physical-chemistry study of spinel ferrites is the understanding of the factors that affect the cationic distribution and the control of it. The inversion degree may depend on the thermal history of the materials and also on particle size effects.

The use of an inorganic nonmagnetic matrix (e.g., amorphous silica) as a host for nanoparticles can provide a way to control morphological, structural, and consequently physical properties of nanocomposite materials. The presence of a

II. EXPERIMENTAL TECHNIQUES AND SAMPLE CHARACTERIZATION

A detailed description of the synthesis procedure is given elsewhere. In addition, nanocomposites may have many advantages from a technological point of view, allowing to improve catalytic, magnetic, magneto-optic, and mechanical properties of the material.

We have prepared cobalt ferrite–silica nanocomposites with a wide range of compositions through a novel synthesis method that combines the traditional sol-gel methods and the nitrate-citrate autocombustion method. In this paper we present a study of samples with 15%, 30%, and 50% w/w of magnetic phase in order to investigate the magnetic properties of these new materials, with particular attention to the effect of silica content; we also focus on the relationship among inversion degree, particle size, and magnetic properties. Finally, we approach the problem of the spin canting in relation to particle size.

A comprehensive structural and textural analysis of the samples by use of x-ray diffraction (XRD) and transmission electron microscopy (TEM) is given elsewhere. Here we give only some results that are necessary for understanding the magnetic data. The XRD patterns showed the presence of the main reflections attributable to the cubic cobalt ferrite phase, superimposed to an amorphous silica halo. The presence of the background due to the amorphous silica did not permit to obtain reliable values of particle size from XRD measurement. The TEM images [Figs. 1(a)–1(c)] show for all the samples the presence of nanocrystalline particles dispersed in a silica host matrix. The particle size distributions [Figs. 1(d)–1(f)] are fitted with log-normal functions and the mean particle sizes ($<D_{TEM}>$) are reported in Table I. The

host matrix may reduce nanoparticle aggregation. In addition, nanocomposites may have many advantages from a technological point of view, allowing to improve catalytic, magnetic, magneto-optic, and mechanical properties of the material.
\( \langle D_{\text{TEM}} \rangle \) values indicate that the increase of ferrite content leads to an increase of particle size and a gradual broadening of size distribution, in agreement with a previous study.\(^{26}\)

**B. Magnetic measurements**

Figures 2(a)–2(c) show magnetization measurements carried out with the ZFC-FC protocol for the samples N15, N30, and N50, respectively. The measurements show for all the samples an irreversible magnetic behavior below a given temperature, called the irreversibility temperature \( T_{\text{irr}} \). \( T_{\text{irr}} \) is related to the blocking of the biggest particles,\(^{27}\) and we define it as the temperature where the difference between \( M_{\text{FC}} \) and \( M_{\text{ZFC}} \), normalized to its maximum value at the minimum temperature (4.2 K), becomes smaller than 3%. The ZFC curves exhibit a maximum and the corresponding temperature \( T_{\text{max}} \) is for noninteracting particles directly proportional to the average blocking temperature with a proportionality constant \((\beta=1–2)\) that depends on the type of size distribution. Therefore, \( T_{\text{max}} \) is related to the blocking of particles with the mean particle size.\(^{28}\) The difference between \( T_{\text{max}} \) and \( T_{\text{irr}} \) provides a qualitative measure of the width of blocking temperature distribution (i.e., of the size distribution in the absence of interparticle interactions).\(^{27}\) In Table I we report \( T_{\text{max}} \) and \( T_{\text{irr}} \) (for the sample N50, \( T_{\text{irr}} \) may be slightly larger than the value given in the Table I, because the measurements were only made up to 325 K and there is no clear coincidence of the FC and ZFC curves below this temperature). For samples N15 and N30, a fitting of the difference between FC and ZFC magnetization curves, which is correlated to the distribution of blocking temperatures,\(^5\) was performed maintaining the anisotropy constant as a fixed parameter and varying the parameters of the distribution volume function (log normal) (Fig. 3, inset). This allowed us to derive the distribution of blocking temperatures (Fig. 3).

\( T_{\text{irr}} \) and \( T_{\text{max}} \) increase with the increase of ferrite content, and this trend can be explained by the increase of particle size and also by an increase of interparticle interactions, as they lead to an increase of the effective anisotropy energy. Actually, the behavior of the FC susceptibility (it increases with decreasing temperature even below \( T_{\text{max}} \)) indicates that the interparticle interactions are negligible in the most diluted sample, N15, and weak in the other two samples, although it is not possible to obtain quantitative information from these measurements. Indeed, for sample N15, the FC magnetization shows a behavior very close to that of an assembly of noninteracting particles, i.e., a Curie-law behavior. On the other hand, the low temperature progressive deviation from a Curie-type behavior (downward curvature) observed in N30 sample and more marked in N50 sample indicates that some weak interparticle interactions (weaker in N30) are present. Indeed, in case of strong interparticle interactions, the FC magnetization would exhibit a temperature independent behavior below \( T_{\text{max}} \), as signature of a collective-type blocking of particle moments.\(^{29}\)

Figures 4(a)–4(c) show measurements of the magnetization as a function of temperature, carried out with the TRM procedure. For all the samples, \( M_{\text{TRM}} \) decreases with increasing temperature, and for N15 and N30 it vanishes above 108 and 180 K, respectively, whereas N50 shows a nonzero value in the whole temperature range, indicating that the largest particles are blocked even at room temperature.

For an assembly of noninteracting particles, the derivative of \( M_{\text{TRM}} \) with respect to temperature gives an estimate of the anisotropy energy barrier distribution.\(^{30,31}\)

\[
f(\Delta E_a) \propto -\frac{dM_{\text{TRM}}}{dT}.
\]

Figures 4(d)–4(f) show the \( \Delta E_a \) distribution (continuous lines) for the three samples, moving towards higher values with increasing particle size, and the fits with a log-normal function (dotted line) for the samples N30 and N15. Actually, the derivative of \( M_{\text{TRM}} \) can be considered as representative of the \( \Delta E_a \) distribution for the N15 and N30 samples, where the interparticle interactions are negligible and very weak, respectively, but not for the N50 sample. Because of the very irregular trends, it is not possible make a reliable fitting for this sample. The obtained distribution for samples N15 and N30 is well consistent with the distribution of blocking temperatures derived from FC/ZFC magnetization measurements.\(^{32}\) The decrease of ferrite content leads to a more regular distribution of anisotropy energy barrier that approaches more and more to log-normal function.
FIG. 3. Distribution of blocking temperatures for samples N15 (a) and N30 (b) derived from the fitting of the temperature dependence of the difference between FC and ZFC magnetizations (inset).

FIG. 4. TRM measurements and distribution of magnetic anisotropy energy for samples N15 [(a) and (d)], N30 [(b) and (e)], and N50 [(c) and (f)].
For noninteracting particles with uniaxial magnetic anisotropy, the superparamagnetic relaxation can be described by the Néel expression:

$$\tau = \tau_0 \exp \left( \frac{K V}{k_B T} \right),$$

(3)

where $k_B$ is the Boltzmann constant, $T$ is the absolute temperature, $K$ is the magnetic anisotropy constant, and $V$ is the particle volume. $\tau_0$ is typically of the order of $10^{-6} - 10^{-13}$ s.\(^{33,34}\) The blocking temperature ($T_B$) can be defined as the temperature for which the relaxation time ($\tau$) is equal to the measuring time of the experimental technique. In practice, samples of small particles always exhibit particle size distributions, and often $T_B$ is defined as the temperature at which 50% of the sample is in the superparamagnetic state.\(^{31,34}\) We can obtain an estimate of the blocking temperature from the distribution of magnetic anisotropy energy barriers, evaluating the temperature at which 50% of the particles overcome their anisotropy energy barriers. In Table II the values of the blocking temperature ($T_B^M$) obtained with this method are reported. Actually, the blocking temperature obtained for N50 is less reliable, due to the presence of very small particles still in the superparamagnetic state at 4.2 K. This is consistent with the size distribution shown in Fig. 1(d).

C. Mössbauer measurements

Mössbauer spectra of noninteracting or weakly interacting magnetic nanoparticles typically consist of a superposition of a sextet due to particles with superparamagnetic relaxation time long compared to the time scale of Mössbauer spectroscopy ($\tau_M \approx 5 \times 10^{-9}$ s) and a doublet due to particles with shorter relaxation times. The relative area of the doublet increases with increasing temperature. However, in samples with strong interactions between the particles, the spectra typically consist of sextets in a broad range of temperatures, but with increasing temperature the lines become broadened and the average hyperfine splitting decreases.\(^{37,38}\)

Figures 6(a)–6(c) show Mössbauer spectra for samples N15, N30, and N50, respectively, in zero applied magnetic field at different temperatures. At low temperatures, the spectra show magnetically split sextets, but with increasing temperature there is a gradual collapse of the six lines to a doublet component because of the fast superparamagnetic relaxation of the nanoparticles. The evolution of the spectra with temperature indicates that the magnetic anisotropy energy is predominant compared to the interaction energy.\(^{37,38}\) The blocking temperature ($T_B^M$) can be defined as the temperature at which 50% of the spectral area is magnetically split.\(^{33}\) The values of $T_B^M$ were estimated by fitting the spectra with the

This is coherent with the presence of weak interactions\(^{34,35}\) and the absence of multiaxial anisotropy as observed in other samples of CoFe$_2$O$_4$ nanoparticles.\(^{36}\) For sample N15, although the particles are not interacting, a lower $M_r/M_s$ value is observed, probably due to the presence of very small particles still in the superparamagnetic state at 4.2 K.
with sextets and doublets and are reported in Table I. The values of $T_B$ decrease with increasing silica content, in agreement with the trend of $T_B$ obtained from magnetization measurement.

The low-temperature spectra show an asymmetry due to a small difference in the Mössbauer parameters of ions in the A and B sites in the spinel structure. In the temperature range of 45–15 K for the N15 sample and between 60 and 15 K for the N50 and N30 samples, it is possible to fit the spectra with sextets that can be ascribed to the iron atoms in the A and B sites. However, because of the overlap of the lines, it was not possible to obtain reliable information about the cationic distribution from these spectra. As expected for small magnetic nanoparticles, we observe a decrease of the magnetic hyperfine field with increasing temperature due to collective magnetic excitations. For non-interacting particles with uniaxial anisotropy, Eq. (4) can in the limit $KV \gg k_B T$ be written as

$$B_{\text{obs}}(T) = B_0 (1 - \frac{k_B T}{2KV}),$$

where $B_0$ is the magnetic hyperfine field in the absence of fluctuations and $\theta$ is the angle between the magnetization vector and the easy direction of magnetization. For non-interacting particles with uniaxial anisotropy, Eq. (4) can in the limit $KV \gg k_B T$ be written as

$$B_{\text{obs}}(T) = B_0 (1 - \frac{k_B T}{2KV}).$$

Figure 7 shows the thermal variation of the average hyperfine field $\langle B_{\text{obs}} \rangle$ (weighted average over A and B components) at temperatures well below the blocking temperature. All three samples show a linear trend in accordance with Eq. (5), and as expected the slope increases with decreasing particle size. The values of the anisotropy constants were estimated using Eq. (5) assuming spherical particle shapes with the diameters given in Table I. The values of $K$, which are reported in Table III, decrease with increasing particle size in

FIG. 6. Mössbauer spectra in zero magnetic field recorded at different temperatures for samples N15, N30, and N50.

accompanying with earlier observations for nanoparticles of α-Fe,41 α-Fe2O3,42 and γ-Fe2O3.43 The estimated values of $K$ may be influenced by interparticle interactions, which can result in apparently larger values of the estimated anisotropy constants.38,40

Mössbauer spectra of ferrites in large applied fields may allow a more reliable distinction between $A$- and $B$-site components than the zero field spectra, because the applied field is usually added to the $A$-site hyperfine field and subtracted from the $B$-site hyperfine field. Therefore, there is less overlap between the two components in the high-field spectra. Furthermore, such spectra can also give information about the magnetic structure. In the presence of an external magnetic field parallel to the gamma ray direction, the relative areas of the six lines give information about the degree of alignment of the magnetization with the applied field. For a thin absorber the relative area of the six lines is given by

$$p = \frac{4 \sin^2 \theta}{1 + \cos^2 \theta}$$

and $\theta$ is the angle between the magnetic field at the nucleus and the gamma ray direction.

Figure 8 shows Mössbauer spectra of samples N15 and N30 at 6 K and of sample N50 at 6 K and at 200 K, all obtained with a magnetic field of 6 T applied parallel to the gamma ray direction. As expected, the spectra are clearly resolved in two main six-line components. Lines 2 and 5 have nonzero intensity and this suggests a noncollinear spin structure, i.e., some of the spins are not aligned parallel or antiparallel to the external magnetic field.6–8

When fitting such spectra with partly overlapping components, it is necessary to apply some constraints on, for example, the relative areas. A finite absorber thickness will result in a ratio between lines 1 and 6 and lines 3 and 4 that is less than 3. In order to minimize the error due to the thickness of the absorbers in the fitting, each spectrum was first fitted with four doublets. For each doublet, the line intensity and line widths were constrained to be equal in pairs and we estimated a ratio of $A_{1/2}/A_{3/4} \approx 2.8$ for all the spectra. This value was then used as a constraint in the fits with sextets. Several fitting procedures were used in order to investigate different possible models. In accordance with the presence of the iron atoms in tetrahedral (A sites) and octahedral (B sites) sites, the spectra were first fitted with two sextets. The parameter $p=A_{2.5}/A_{3.4}$ was free, assuming that

![FIG. 8. Mössbauer spectra in an external magnetic field of 6 T, recorded at 6 K for samples N15 and N30 and at 6 K and 200 K for sample N50.](image)

the canting angle for the magnetic moments in the $A$ and $B$ sites are two independent parameters. The linewidths and line intensities were fixed to be equal in pairs. However, this model seemed to be too simple, and, in particular, the fitting of the positions of lines 2 and 5 was not satisfactory, indicating that other components were present. The spectra were therefore fitted with three sextets. The best results were obtained utilizing a model similar to that used previously for maghemite nanoparticles, tin-doped maghemite,44 and MnZn ferrite.45 Thus it was assumed that some of the iron atoms were in perfect ferrimagnetic local environments, and in accordance with this the relative areas of lines 2 and 5 were constrained to zero for two sextets (area ratio of 2.8:0.1:1.0:2.8) corresponding to $A$ (sextet 1) and $B$ (sextet 2) sites. A third sextet (sextet 3) was introduced to represent ions with canted spins, and in this component the parameter $p=A_{2.5}/A_{3.4}$ was free (area ratio of 2.8:1:1:1:2.8). In all three sextets the linewidths and line intensities were constrained to be pairwise equal. The Mössbauer parameters obtained from these fits are given in Table IV.

In the high-field spectra, obtained at low temperature, the values of total field at the nuclei, $B_{HF}$, the isomer shifts ($\delta$), and the quadrupole shifts ($\epsilon$) for each sextet are very similar for the three samples, and this indicates that the magnetic structure of the nanoparticles is quite similar for all of them. In all samples, sextet 2 and sextet 3 show values of the isomer shifts typical for octahedrally coordinated Fe$^{3+}$ in spinels but larger than that of sextet 1, which is typical for tetrahedrally coordinated Fe$^{3+}$. This indicates that the canted spins are mainly located in the $B$ sites.

At low temperatures the recoilless fractions for iron ions in the $A$ and $B$ sites are essentially equal,46 and therefore the area of the different components can give information about the cationic distribution. The ratio between $A$ (sextet 1) and $B$ (sextet 2 and sextet 3) sites ($\alpha$) is remarkably similar for all the samples, indicating similar cationic distributions in the three samples. The $\alpha$ values are lower than those of a previous Mössbauer study of CoFe$_2$O$_4$ nanoparticles, and

this difference can be due to the preparation method of the material\(^{46}\) and in particular, to the thermal treatment at high temperature. From these ratios, utilizing the formula (CoFe\(_{1-x}\))[Co\(_{1-y}\)Fe\(_x\)]\(_4\)^{47}\ make \( \approx 3–7\)\(^{34}\), while the widths of the lines increase by about 50% when the temperature is raised to 200 K. The decrease of \( A_{2,5} \) indicates transverse relaxation with the time scale of Mössbauer spectroscopy.\(^{44,45,48}\)

IV. DISCUSSION

Mössbauer spectroscopy and magnetization measurement have significantly different time scales, and for this reason the blocking temperatures estimated from the two techniques differ considerably. Inserting the time scales of magnetization measurement \( (\tau_m \approx 100 \text{ s}) \) and Mössbauer spectroscopy \( (\tau_m = 5 \times 10^{-9} \text{ s}) \) in Eq. (3) and values of \( \tau_0 = 10^{-10} \text{–} 10^{-12} \text{ s} \) typical for ferrimagnetic materials in Eq. (3), one finds that the ratio \( T_B^M/T_B^M \) should be in the range of 3–7.\(^{34}\) Considering that the value of \( T_{\text{max}} \) in ZFC magnetization measurements may be greater than \( T_B^M \) by a factor \( \beta \approx 1–2 \), the ratio \( T_B^M/T_B^M \) would be in the range of 2–7.\(^{34}\) In Table III reported are the ratios \( T_B^M/T_B^M \) and \( T_B^M/T_{\text{max}} \) for all the samples. Considering the experimental errors, N15 and N30 show values that are in quite good agreement with the theoretical calculations, while for sample N50 a lower value was obtained. This behavior of the more concentrated sample can be due to some interparticle interactions (a lower measuring time dependence of the blocking temperature is expected in this case), but an underestimate of \( T_B^M \) may also play a role, since TRM measurement shows that there are still particles in the blocked state at 325 K and the value of the blocking temperature obtained from the anisotropy energy barrier distribution does not take these particles into account.
account. Anyway, both the trend of the FC curve and the Mössbauer data suggest that the interparticle interactions are weak in this sample.

The magnetic properties of CoFe$_2$O$_4$ are strongly dependent on the distribution of the iron and cobalt ions in the A and B sites. As a rule, even small changes in the cationic distribution can result in substantial changes of magnetic moments and of the magnetic anisotropy.\(^{50}\) Usually, bulk cobalt ferrite has a partially inverse structure where the ratio $\alpha$ has been found to vary from 0.6 to 0.87, depending on the thermal history of the sample.\(^{46}\) In nanosized particles the ratio between iron atoms located in A sites and B sites has been found lower, in the range from 0.67 (Refs. 36 and 51) and 0.5 (Ref. 47) for different synthesis methods. All the samples investigated in this paper show $\alpha$ values around 0.36. The nearly constant value of $\alpha$ for all the samples is a very important result, because usually a reduction of the di-

Fe$^{3+}$ and Co$^{2+}$ ions have a moment of 5\(\mu_B\) and 3\(\mu_B\), respectively, and neglecting the spin canting, our samples have a magnetic moment per unit chemical formula of about 4.9\(\mu_B\) that corresponds to a saturation magnetization of 116 A m$^2$ kg$^{-1}$. All the samples show a significant reduction of $M_s$ with respect to this theoretical value. Sample N15 shows a larger reduction, probably due to the presence of particles still in the superparamagnetic state at low temperature. The reduction of $M_s$ can be explained by to the presence of a noncollinear spin structure, as shown by the high magnetic field Mössbauer spectra.

Samples N30 and N15 show remarkably similar values of $A_{2,3,5}$, within the experimental error, while sample N50 presents a slightly larger canting. This result is quite interesting in the general discussion about the noncollinear structure in the magnetic nanoparticles. In fact, the presence of similar canting in the three samples with the largest degree of canting in the largest particles indicates that the spin canting is not a surface phenomenon but that it is an effect that is more or less uniform throughout the volume of the particles.

V. CONCLUSIONS

The dispersion of cobalt ferrite nanoparticles in a silica matrix through sol-gel autocombustion method allows to obtain assemblies of weakly interacting particles. The sol-gel autocombustion synthesis results in nanoparticles with a cationic distribution that is independent of the particle size (7–28 nm) and with a very low inversion degree that leads to important modifications of the magnetic properties of the material. We have determined the magnetic anisotropy constants of cobalt ferrite nanoparticles from the temperature dependence of the magnetic hyperfine splitting in Mössbauer spectra at low temperatures and from the blocking temperatures estimated from Mössbauer spectroscopy and magnetization measurements. The values estimated by the two methods are in good agreement, and it is found that the anisotropy constant increases with decreasing particle size. However, surprisingly, it is found that the anisotropy constants are smaller than the bulk value. We show that this can be explained by a cationic distribution, which differs considerably from that usually found in bulk cobalt ferrite.

Finally, the samples N15 and N30 show large but similar fractions of canted spins, indicating that the fraction of canted spins is only weakly dependent on the particle size in the range of 6–17 nm. This result indicates that the spin canting is not simply a surface phenomenon but also occurs in the interior of the particles.
