1           **1     Abstract**

2  
3  
4     A risk assessment tool for contaminated sites in low-permeability fractured media is  
5  
6     developed, based on simple transient and steady-state analytical solutions. The Discrete  
7  
8     Fracture (DF) tool, which explicitly accounts for the transport along fractures, covers different  
9  
10    source geometries and history and can be applied to a wide range of compounds. The tool  
11  
12    successfully simulates published data from short duration column and field experiments. The  
13  
14    use for risk assessment is illustrated by three typical risk assessment case studies, involving  
15  
16    pesticides, chlorinated solvents, benzene and MTBE. The model is compared with field data  
17  
18    and with results from a simpler approach based on an Equivalent Porous Media (EPM). Risk  
19  
20    assessment conclusions of the DF and EPM approaches are very different due to the early  
21  
22    breakthrough, long term tailing, and lower attenuation due to degradation associated with  
23  
24    fractured media. While the DF tool simulates the field data, it is difficult to conclude that the  
25  
26    DF model is superior to an EPM model because of a lack of long term monitoring data.  
27  
28  
29    However, better agreement with existing field data by the DF model using observed physical  
30  
31    fracture parameters favors the use of this model over the EPM model for risk assessments.

48           **2     Introduction**

49  
50  
51        Many contaminated sites occur in areas with low-permeability fractured media (such as  
52  
53        clay-rich glacial deposits) at the land surface. Fractured media are important to consider when  
54  
55        assessing risk to the groundwater at contaminated sites, because of the fast downward  
56  
57        pathway along the fractures and the diffusion into the porous matrix. The porous matrix can

63  
64  
65

1 act as a long term secondary source that leaches through back diffusion to the fractures and  
2 the underlying aquifer (Parker et al., 2008). However, in most screening tools for risk  
3 assessment (e.g., ROME (ANPA, 2002), BIOBALANCE (Kamath, 2006), RISC4 (Spence,  
4 2001), CatchRisk (Troldborg et al., 2008)), fractures are not explicitly considered and instead  
5 are represented by an equivalent porous media (EPM) with equivalent hydraulic conductivity  
6 and porosity. Although such simplifications can be relevant in some cases, particularly for  
7 small fracture spacings (typically between 1 and 40 cm) (McKay et al., 1997; Pankow et al.,  
8 1986; van der Kamp, 1992), transport processes causing fast breakthrough and the large  
9 storage capacity of low-permeability fractured media are generally not well represented. The  
10 migration of contaminants is controlled by advection in the fracture, exchange between the  
11 fracture and the matrix and molecular diffusion in the low-permeability matrix. In addition  
12 degradation processes for organic contaminants add to the complexity. Many studies have  
13 shown that these phenomena cannot be properly modeled by an EPM approach and require  
14 the use of discrete fracture models (DF) (e.g. Jørgensen et al., 1998; Sidle et al., 1998).

32  
33  
34 Fracture networks can be very complex and many numerical models have been developed  
35 to simulate flow and contaminant transport in such systems (e.g., Chambon et al., 2010;  
36 Slough et al., 1999; Sudicky and McLaren, 1992; Therrien and Sudicky, 1996). However in a  
37 regulatory context for risk assessment of contaminated sites, simple screening models with  
38 limited data demand are often necessary. Therefore analytical solutions that include the main  
39 processes but are not too data demanding are preferable.

45  
46  
47  
48 Many analytical solutions are available for simulating contaminant transport in a single or  
49 parallel fractures system, accounting for advection and dispersion along the fracture,  
50 molecular diffusion and sorption within the matrix, as well as first order radioactive decay in  
51 both the fracture and matrix (e.g., Shih, 2007; Sudicky and Frind, 1982; Tang et al., 1981).

1 required for risk assessment (constant source, source removal and contaminant trapped in the  
2 fractured media). They are also not coupled to an underlying groundwater system, which is  
3 required for risk assessment applications. In the current work/study the solution of Tang et al.  
4 (1981) is modified to include the required conditions. The full set of analytical solutions for  
5 the risk assessment model is presented in a user-friendly Microsoft Excel spreadsheet to  
6 enable use by non-specialist.

10  
11  
12  
13

14 The modification of published analytical solutions is fairly straight forward and so the  
15 main contribution of this paper is the demonstration of the use of the solutions for risk  
16 assessment and comparison with observed data for a number of typical risk assessment cases.  
17 The validity of risk assessment models is generally difficult to document because of the lack  
18 of appropriate (long-term, over decades - centuries) observed data for comparison (e.g.  
19 Fischer et al., 2010; Kohne et al., 2009; Tait et al., 2004b; Troldborg et al., 2008). Models for  
20 flow and transport through low-permeability fractured media have been compared with  
21 column and field data of short duration (typically hours to days, e.g. Jørgensen et al., 1998;  
22 2002; McKay et al., 1993b), but the long term leaching due to slow back diffusion from the  
23 matrix to the fracture system has not been documented because of the long timeframes. In this  
24 study, the developed tool is compared to controlled experimental data and to field data from  
25 real case studies and the suitability of the models for risk assessment is discussed. Finally, the  
26 developed DF model is compared with EPM model using datasets from three cases studies  
27 and the applicability of each tool for risk assessment in fractured media is discussed.

### 49 **3 Conceptual models**

50 The physical system is illustrated in Figure 1a with a low-permeability fractured media  
51 overlying an aquifer. The developed risk assessment tool focuses on fully saturated fractured  
52 media, and transport of gas phase is not considered. This is a realistic assumption, as the low-  
53 permeability matrix will retain water and will usually be fully saturated even when above the

1 water table, and so gas transport is limited to fracture zones and is negligible. The real  
2 fracture network is simplified in Fig. 1b, so that only fully penetrating vertical fractures are  
3 considered and a homogeneous fracture spacing is assumed. These simplifications of the  
4 natural network are motivated by the scope of this study, which focuses on downward  
5 transport from fractured media to the aquifer, so the horizontal features are of less importance.  
6 Although some analytical solutions exist for the case of parallel fractures, they are quite  
7 complex and numerical integration is required. For risk assessment purposes, simple  
8 computational approaches which can be implemented in spreadsheets, GIS etc are preferred.  
9 Therefore the geometry is further simplified to consider only a single fracture surrounded by a  
10 semi-infinite matrix. For large fracture spacings ( $2B > 1 - 1.5$  m), this simplification is  
11 reasonable (see Supplementary information).

29 **Fig. 1.** a) Physical system considered in this study: a low-permeability fractured media overlies an aquifer. The  
30 area of interest is shown with the dashed box. b) Simplification of the fractured media for modeling: the fractures  
31 are assumed to be fully penetrating and equally spaced. c) Further simplification with the case of a single  
32 fracture embedded in a semi-infinite porous matrix.  
33  
34  
35  
36  
37  
38  
39

40 Based on this physical system, the risk assessment tool is developed with three conceptual  
41 models for the source geometry and history. Model 1 represents the source overlying the  
42 fractured media, with a constant concentration, for either a known duration (model 1a in Fig.  
43 2), for example an underground storage tank that has been removed, or for infinite time  
44 (model 1b in Fig. 2). In model 2 the source has been removed, but contaminant trapped in the  
45 clay below the former source continues to leach for many years afterwards (model 2 in Fig.  
46 2). This case can be approximated with a zero input concentration at the top of the fracture  
47 and a homogeneous initial concentration in the porous matrix. Model 2 is useful when the  
48 history of contamination (amount, length, concentration, geometry) of the fractured media is

unknown and the only available data are the measured concentrations in the porous matrix.

**Fig. 2.** Conceptual sketch of the three models (top). Model 1a and 1b represent a source overlying the fractured media, for a years in case of model 1a and for infinite time in case of model 1b. Model 2 represents the case of contaminant trapped uniformly in the porous matrix.

## 4 Mathematical model

The conceptual models have the same physical settings and only the boundary and initial conditions change. The mathematical model is based on the following set of assumptions: (i) the system is fully saturated (ii) linear reversible and instantaneous equilibrium partitioning between dissolved and sorbed phases, (iii) mass transport along the fracture is one-dimensional (iv) dispersion along the fracture is neglected, (v) advection in the porous matrix is neglected, (vi) transport in the matrix is perpendicular to the fracture, (vii) degradation can be described as a first-order process and only occurs in the water phase, (viii) degradation products are not considered and (viii) separate liquid phase transport is not included.

### 4.1 Governing equations

The one-dimensional transport equation in a vertical fracture is, under the assumptions above (Tang et al., 1981):

$$R_f \frac{\partial C_f}{\partial t} + v_f \frac{\partial C_f}{\partial z} + \frac{Q_m}{b} + \lambda C_f = 0 \quad (1)$$

where  $C_f$  is the solute aqueous concentration in the fracture ( $M/L^3$ ),  $R_f$  is the retardation coefficient on the fracture surface (-),  $v_f$  is the groundwater velocity in the fracture ( $L/T$ ),  $z$  is the special coordinate along the fracture ( $L$ ),  $Q_m$  is the mass transfer flux at the fracture-matrix interface ( $M/T/L^2$ ),  $b$  is the half aperture of the fracture ( $L$ ), and  $\lambda$  is the first-order degradation rate ( $1/T$ ).

The transport in the matrix perpendicular to the fracture is described by the one-dimensional diffusion equation:

$$R_m \frac{\partial C_m}{\partial t} - D_m \frac{\partial^2 C_m}{\partial x^2} + \lambda C_m = 0 \quad (2)$$

where  $C_m$  is the aqueous concentration in the matrix ( $M/L^3$ ),  $R_m$  is the retardation factor due to sorption and  $D_m$  is the effective diffusion coefficient ( $L^2/T$ ). The effective diffusion coefficient is defined as  $D_m = \tau D_d$  (Bear, 1972), with  $\tau$  the matrix tortuosity (-) and  $D_d$  the free diffusion coefficient in water ( $L^2/T$ ). As a first approximation,  $\tau$  can be assumed equal to the matrix porosity  $\phi$  (Parker et al., 1994).

Linear sorption is assumed in both the matrix and fracture and the retardation coefficients are  $R_{m,i} = 1 + \frac{\rho_b}{\phi} K_{d,i}$  and  $R_f = 1 + \frac{K_f}{b}$ , where  $\rho_b$  is the bulk density ( $M/L^3$ ),  $\phi$  is the porosity of the matrix material,  $K_d = f_{oc} K_{oc}$  is the distribution coefficient ( $L^3/M$ ) with  $f_{oc}$  being the fraction of organic carbon,  $K_{oc}$  the partition coefficient with respect to organic matter, and  $K_f$  the distribution coefficient for the fracture wall (L) (Freeze and Cherry, 1979). In this paper,  $R_f$  is assumed equal to retardation in the matrix  $R_m$  (Jørgensen et al., 1998; 2002).

The coupling between the matrix and fracture equations is provided by a requirement of continuity of concentration and flux at the fracture-matrix interface where the mass transfer flux  $Q_m$  at the matrix-fracture interface is defined by Fick's first law:

$$Q_m = -\phi D_m \left. \frac{\partial C_m}{\partial x} \right|_{x=b} \quad (3)$$

and  $C_m(b, z, t) = C_f(z, t)$  at the fracture-matrix interface. The boundary conditions for Eq.(1) and (2) depend on the model considered (see Appendix).

The analytical solutions to Eq.(1) and (2) with different initial and boundary conditions are found using the Laplace transform and details are presented in the Appendix.

## 4.2 Model 1 – Source overlying fractured media

The analytical solution to conceptual model 1a shown in Fig. 2 is:

$$\frac{C_f}{C_0} = \begin{cases} 0 & T' < 0 \\ \frac{1}{2} \exp\left(-\frac{\lambda z}{v_f}\right) \left[ \exp\left(-\frac{H}{A} \sqrt{\frac{\lambda}{R_m}}\right) \operatorname{erfc}\left(\frac{H}{2AT'} - \sqrt{\frac{\lambda}{R_m}} T'\right) \right. \\ \quad \left. + \exp\left(\frac{H}{A} \sqrt{\frac{\lambda}{R_m}}\right) \operatorname{erfc}\left(\frac{H}{2AT'} + \sqrt{\frac{\lambda}{R_m}} T'\right) \right] & T' > 0 \text{ and } T'' < 0 \\ \frac{1}{2} \exp\left(-\frac{\lambda z}{v_f}\right) \left[ \exp\left(-\frac{H}{A} \sqrt{\frac{\lambda}{R_m}}\right) \operatorname{erfc}\left(\frac{H}{2AT'} - \sqrt{\frac{\lambda}{R_m}} T'\right) \right. \\ \quad + \exp\left(\frac{H}{A} \sqrt{\frac{\lambda}{R_m}}\right) \operatorname{erfc}\left(\frac{H}{2AT'} + \sqrt{\frac{\lambda}{R_m}} T'\right) \\ \quad - \exp\left(-\frac{H}{A} \sqrt{\frac{\lambda}{R_m}}\right) \operatorname{erfc}\left(\frac{H}{2AT''} - \sqrt{\frac{\lambda}{R_m}} T''\right) \\ \quad \left. - \exp\left(\frac{H}{A} \sqrt{\frac{\lambda}{R_m}}\right) \operatorname{erfc}\left(\frac{H}{2AT''} + \sqrt{\frac{\lambda}{R_m}} T''\right) \right] & T'' > 0 \end{cases} \quad (4)$$

$$\frac{C_m}{C_0} = \begin{cases} 0 & T' < 0 \\ \frac{1}{2} \exp\left(-\frac{\lambda z}{v_f}\right) \left[ \exp\left(-W \sqrt{\frac{\lambda}{R_m}}\right) \operatorname{erfc}\left(\frac{W}{2T'} - \sqrt{\frac{\lambda}{R_m}} T'\right) \right. \\ \quad \left. + \exp\left(W \sqrt{\frac{\lambda}{R_m}}\right) \operatorname{erfc}\left(\frac{W}{2T'} + \sqrt{\frac{\lambda}{R_m}} T'\right) \right] & T' > 0 \text{ and } T'' < 0 \\ \frac{1}{2} \exp\left(-\frac{\lambda z}{v_f}\right) \left[ \exp\left(-W \sqrt{\frac{\lambda}{R_m}}\right) \operatorname{erfc}\left(\frac{W}{2T'} - \sqrt{\frac{\lambda}{R_m}} T'\right) \right. \\ \quad + \exp\left(W \sqrt{\frac{\lambda}{R_m}}\right) \operatorname{erfc}\left(\frac{W}{2T'} + \sqrt{\frac{\lambda}{R_m}} T'\right) \\ \quad - \exp\left(-W \sqrt{\frac{\lambda}{R_m}}\right) \operatorname{erfc}\left(\frac{W}{2T''} - \sqrt{\frac{\lambda}{R_m}} T''\right) \\ \quad \left. - \exp\left(W \sqrt{\frac{\lambda}{R_m}}\right) \operatorname{erfc}\left(\frac{W}{2T''} + \sqrt{\frac{\lambda}{R_m}} T''\right) \right] & T'' > 0 \end{cases} \quad (5)$$

where

$$A = \frac{bR_f}{\phi\sqrt{R_m D_m}}$$

$$H = \frac{R_f z}{v_f}$$

$$W = \frac{H}{A} + \sqrt{\frac{R_m}{D_m}}(x-b)$$

$$T' = \sqrt{t-H}$$

$$T'' = \sqrt{t-a-H}$$

For model 1b in Fig. 2, the solution reduces to the two first terms, for infinite T'' (the source is not removed).

Furthermore a steady-state concentration can be calculated for model 1b:

$$\frac{C_f}{C_0} = \exp\left(-\frac{\lambda z}{v_f}\right) \exp\left(-\frac{H\sqrt{\lambda/R_m}}{A}\right) \quad (6)$$

$$\frac{C_m}{C_0} = \exp\left(-\frac{\lambda z}{v_f}\right) \exp\left(-\sqrt{\lambda/R_m} W\right)$$

An analytical solution to model 1b (constant input concentration) for radioactive decay was presented by Tang et al. (1981). The solution was modified to account for the fact that degradation occurs in the aqueous phase only, which can result in significantly higher leaching concentrations for sorbing compounds.

#### 4.3 Model 2 – Contaminated fractured media with uniform initial concentration

This model differs from the previous one, as the matrix is assumed to be initially contaminated and the water entering the system at the top of the fracture is devoid of contaminant.

The solution for this model is given by:

$$\frac{C_f}{C_i} = \begin{cases} \exp\left(-\lambda/R_m t\right) - \left(\exp\left(-\lambda z/v_f\right) \exp\left(-\lambda/R_m T'^2\right) \operatorname{erfc}\left(\frac{H}{2AT'}\right)\right) & T' > 0 \\ \exp\left(-\lambda/R_m t\right) & T' < 0 \end{cases} \quad (7)$$

$$\frac{C_m}{C_1} = \begin{cases} \exp\left(-\lambda/R_m t\right) - \left(\exp\left(-\lambda z/v_f\right) \exp\left(-\lambda/R_m T'^2\right) \operatorname{erfc}\left(\frac{W}{2T'}\right)\right) & T' > 0 \\ \exp\left(-\lambda/R_m t\right) & T' < 0 \end{cases} \quad (8)$$

#### 4.4 Coupling to groundwater

The models presented in this study can be used to assess the leaching concentration from a fractured media to an underlying aquifer. The main objective when performing risk assessment is often to calculate the concentration in the aquifer and to compare this value with the maximum allowed contaminant levels (MCLs). Therefore it is necessary to couple the fractured media leaching model to a simple groundwater model. In many risk assessment tools, the contamination of groundwater is calculated from the contaminant mass discharge from the contaminant source to the groundwater (Einarson and Mackay, 2001; Tait et al., 2004a; Troldborg et al., 2008). Under the assumption of complete mixing of the leaching flux at the bottom of the fractured media, the overlying fractured system can be seen as a contaminant source located at the water table for the aquifer. The mass discharge to groundwater can thus be calculated:

$$J_{\text{frac-gw}} = C_f A_{\text{cont}} I \quad (9)$$

where  $C_f$  is the leaching concentration at the fracture outlet,  $A_{\text{cont}}$  is the contaminated area at the water table and  $I$  is the net infiltration rate.  $A_{\text{cont}}$  can be approximated by the contaminant source area overlying the fractured media for model 1, and by the area over which the fractured media is contaminated for model 2.

The aquifer concentration at a chosen distance from the source can then be calculated using the dilution factor model (DAF) from US EPA (1996), which considers simple mixing with the clean groundwater:

$$C_{aq} = \frac{J_{\text{frac-gw}}}{A_{\text{cont}} I + K_{aq} i_{aq} d_m \sqrt{A_{\text{cont}}}} = \frac{C_f}{DAF} \quad (10)$$

$$\text{where } DAF = 1 + \frac{K_{aq} i_{aq} d_m}{I \sqrt{A_{\text{cont}}}}$$

where  $K_{aq}$  is the hydraulic conductivity of the aquifer (L/T),  $i_{aq}$  is the hydraulic gradient in the aquifer and  $d_m$  is the mixing zone depth. This concentration can be compared with measured concentrations in the aquifer, using the screen length as mixing zone depth, to assess how the model compares with field observations.

#### 4.5 Choice of parameters

The parameters for a specific contaminant ( $D_d$ ,  $K_d$ ,  $\lambda$ ) can be found in databases for risk assessment (e.g., Danish EPA, 2002a; US EPA, 2010a), while the parameters for the physical properties of the fractured media can be found in the literature. Extensive fracture mapping and hydraulic experiments have been performed in fractured clay tills in Denmark and North America (Fredericia, 1990; Jakobsen and Klint, 1999; Jørgensen et al., 2002; 2003; 2004; Klint and Gravesen, 1999; McKay et al., 1993b; 1999; McKay and Fredericia, 1995) and the results of these studies can be used to provide typical fracture spacing, aperture and matrix porosity when site specific parameters are lacking. The measured matrix porosity ( $\phi$ ) ranged between 0.23 and 0.35 so a typical value of 0.3 will be used in the case studies. The fracture flow velocity ( $v_f$ ) can be calculated from the fracture aperture (2b) and the vertical hydraulic gradient ( $i$ ) using the cubic law (Snow, 1969). Measurements of fracture apertures are limited in the literature, but this parameter can be estimated from the bulk hydraulic conductivity (ranged between  $10^{-9}$  and  $6 \times 10^{-8}$ , with typical value  $10^{-8}$  m/s (Fredericia, 1990)) and the fracture spacing (2B) (McKay et al., 1993a), under the assumption of zero flow in the matrix, which is reasonably approximated by typical hydraulic conductivities of  $<10^{-9}$  m/s for the matrix of clayey till. The fracture spacing was shown to increase with increasing depth from around 1 meter at 5 mbs to 2-3 meters at 8.5 mbs (Jørgensen et al., 2003; McKay et al.,

1993a) and value of 5 meters is suggested for thicker clayey tills (Jørgensen et al., 2004). For such fracture spacings, the assumption of a single fracture model is reasonable (see Supplementary information).

In the case studies below the typical parameters are used, except when site specific data were available (for ex. matrix porosity in Case I).

#### 4.6 1D-EPM model

In order to assess the need for a specific tool for risk assessment in fractured media, the developed model is compared to a one-dimensional EPM model defined by:

$$R_m \frac{\partial C}{\partial t} = D_z \frac{\partial^2 C}{\partial z^2} - v_{EPM} \frac{\partial C}{\partial z} - \lambda C \quad (11)$$

where  $v_{EPM}$  is the flow velocity in the equivalent porous media (depending on the bulk hydraulic conductivity, the hydraulic gradient and the equivalent porosity) and the longitudinal hydrodynamic dispersion  $D_z$  is defined as:

$$D_z = \alpha_L v_{EPM} + D_m \quad (12)$$

The analytical solutions for Eq.(11) for conceptual models 1a, 1b and 2 are given by van Genuchten and Alves (1982, p.60).

## 5 Results

### 5.1 Comparison of the three fracture models

The three models (1a, 1b and 2) are applied for the case of a conservative ( $\lambda = 0$ ) and a degradable compound ( $\lambda = 0.2 \text{ y}^{-1}$ ) with the parameters shown in Table 1.

**Table 1**

Parameters used in DF tool

Parameter	Value
Fracture aperture $2b$ ( $\mu\text{m}$ )	25
Matrix porosity (-)	0.3
Velocity in fracture (m/y)	2000
Diffusion coefficient in matrix $D_m$ ( $\text{m}^2/\text{y}$ )	$10^{-3}$
Retardation factor $R_m = R_f$	5
Degradation rate $\lambda$ ( $\text{y}^{-1}$ )	0 – 0.2

For model 1a, the source is assumed to have overlain the fractured media for 20 years ( $a = 20$  years in Eq.(4)).

**Fig. 3.** Breakthrough curves for the three models at  $z = 5$  m for a conservative ( $\lambda = 0$ ) and a degradable compound ( $\lambda = 0.1 \text{ y}^{-1}$ ). For model 1a, the source is released between  $t = 0$  and  $t = 20$  years.

In many risk assessment applications, only steady state model output is considered. But Fig. 3 shows that the transient behavior is important, especially for the case of conservative compounds, where the breakthrough curves do not reach steady-state ( $C = C_0$ ) after a hundred years. For the case of biodegradable compounds, it takes 40 years to reach steady-state for model 1b.

Fig. 3 also shows that microbial degradation is an important attenuation process. Degradation shortens the leaching time to an underlying aquifer from more than 100 years to less than 60 years for models 1a and 2 for both a conservative and a slowly biodegradable compound. Furthermore it can be seen that the outlet concentration decreases quickly for model 2, due to the mass transfer limitations from matrix to fracture. This phenomenon contributes to the attenuation of contaminants in the fractured media and needs to be taken into account when assessing risk to groundwater.

## 5.2 Comparison with experimental data

1  
2  
3 In order to verify the ability of the developed model to simulate fracture flow problems, it  
4 was applied to a range of published experimental datasets. The application to column  
5 experimental data from Jørgensen et al. (1998) is illustrated in this section. Undisturbed  
6 columns of fractured clayey till were used in tracer experiments with chloride and the  
7 pesticide MCP (Jørgensen et al. 1998). Chloride is a conservative tracer, while MCP can  
8 sorb onto the clay matrix. Both tracers were injected in steady-state water flows through three  
9 columns containing sediments sampled from different depths in the field. The three columns  
10 are characterized by different fracture systems (spacing and aperture). In Jørgensen et al.  
11 (1998), the numerical FRACTRAN model was used to simulate the breakthrough curves, and  
12 the same parameters are used as input for the DF tool (Table 2). The measured and simulated  
13 breakthrough curves for one column are shown in Fig. 4. The model simulates the  
14 experimental data in all three columns well, both for conservative and sorbing tracers. The  
15 results are comparable to those obtained using FRACTRAN, which also accounted for flow in  
16 the matrix and parallel fractures.

17  
18 The DF tool also successfully simulated the column and field experimental data of Hinsby  
19 et al. (1996) (column: chloride and bacteriophages), Tang and Weisbrod (2009) (column:  
20 bromide and lithium), Jørgensen et al. (2002) (field: bromide and MCP) and Mortensen et al.  
21 (2004) (field: chloride, DBA and fluorescent dyes) (data not shown).

22  
23 **Fig. 4.** Simulated and measured breakthrough curves for MCP and chloride in undisturbed column of fractured  
24 clayey till. Data from Jørgensen et al. (1998).

**Table 2**  
Parameters used in the case studies

Parameters	Column (Jørgensen et al., 1998)	Case I (BAM <sup>a</sup> )	Case II (TCE <sup>b</sup> )	Case III (MTBE/benzene)

### 5.3 Case studies for risk assessment in fractured media

The experiments presented in the previous section are of short duration (from several hours to days), and are focused on the validation of the conceptual model of fast contaminant breakthrough through fractures and retardation due to diffusion into the matrix. The long term leaching (over years and decades) due to slow back diffusion from the matrix to the fracture system has not been documented with observed data in the literature, because of the long timeframes. In the context of risk assessment, contamination has often occurred over long time periods and the risk should be assessed many years/decades later.

1 To illustrate the use of the models in risk assessment, they are applied to three case  
2 studies. The case studies are chosen to illustrate the use of the three conceptual models (Fig.  
3  
4 1) for three commonly found pollutants (pesticides, BTEX and chlorinated solvents). The  
5 parameters used in the case studies are summarized in Table 2.  
6  
7

### 8 9 10 **5.3.1 Case I – Diffusive sources of pesticides in a Danish catchment**

11  
12 The DF tool is applied to assess the risk posed to groundwater and drinking water wells  
13 by the pesticide dichlobenil (DCB), which was used in Denmark between 1966 and 1997  
14 (Holtze et al., 2008). DCB is known to degrade to 2,6-dichlorobenzamide (BAM) under  
15 aerobic conditions in the upper part of the soil (mainly above 3 meters), with a half-life  
16 constant of about 0.5-3 year (Clausen et al., 2007). Below this depth, DCB degradation  
17 decreases very quickly with increasing depth. BAM is viewed as recalcitrant in deeper soils  
18 and aquifers (Broholm et al., 2001; Holtze et al., 2008). Monitoring data from the waterworks  
19 in the catchment shows that BAM is found in many wells during the period 1995-2009, but  
20 the actual breakthrough time is unknown.

30  
31  
32  
33  
34

35 In this study, the DF tool is used to assess the risk posed by BAM, resulting from the  
36 application of DCB on treated soils. It is assumed that all DCB applied on the soil is degraded  
37 to BAM within the upper three meters of the soil. This assumption is justified by the fact that  
38 DCB is rarely found below 3 meters (Danish EPA, 2002b). The DF tool is then applied to  
39 vertical transport of BAM from 3 to 8 mbs through 5 meter thick fractured clayey till, which  
40 is the average thickness in the studied area. The parameters are obtained from a study  
41 performed in the catchment by Danish EPA (2002b). The input BAM concentration ( $C_0$ ) is  
42 estimated to be 4600  $\mu\text{g/L}$ , based on an effective DCB application of 5kg/ha/year. The  
43 sorption coefficient  $K_d$  for BAM in anaerobic clayey till is estimated to be 0.93 L/kg at the  
44 site (Clausen et al., 2004). The bulk density ( $\rho_b$ ) and the porosity ( $\phi$ ) of the clay matrix are  
45 estimated to be 1.95 kg/L and 0.25, respectively. The retardation coefficient in the matrix is

1 calculated to be  $R_m = 8.3$ . The free diffusion of BAM in water is  $4.32 \times 10^{-10} \text{ m}^2 \cdot \text{s}^{-1}$  (Jørgensen  
2 et al., 2003) and the tortuosity is assumed equal to the porosity. The net infiltration through  
3 the fractured till is estimated to be 120 mm/year. The fracture spacing and aperture are  
4 assumed to be 1 m and 25  $\mu\text{m}$ , respectively, which are typical values for Danish fractured  
5 clayey till (McKay et al., 1999). An EPM model is also applied for comparison, with default  
6 parameters for the porosity (equal to the total matrix porosity, 25%) and the longitudinal  
7 dispersivity ( $\alpha_L = 0.1 \text{ m}$ ).

13  
14  
15

16 The outputs from the two approaches are used to calculate the expected concentration in  
17 the drinking water wells, neglecting the travel time from the sources to the wells. The mass  
18 discharge from the sources is calculated using the source area and the infiltration data, and is  
19 divided by the yearly pumping rate at the waterworks (800,000  $\text{m}^3/\text{year}$ ), assuming that all  
20 contaminated water reaches the supply wells. The results in Fig. 5a show that the presence of  
21 pesticides in the wells is well predicted by the DF tool (thick line). BAM shows a fast  
22 breakthrough and is expected to persist in the drinking water wells (EC threshold limit of 0.1  
23  $\text{mg} \cdot \text{L}^{-1}$  for single pesticide residues in groundwater) until 2050. In contrast the EPM model  
24 using the default parameters (dotted line) cannot simulate the data, predicting a BAM  
25 breakthrough starting in 2015. Fig. 5a shows that the EPM model can simulate the presence of  
26 BAM in 1995 using lower effective porosity and/or higher dispersivity values (dashed lines).  
27 Decreasing the porosity results in an earlier breakthrough and the EPM behaves as a “plug-  
28 flow” model. An increased dispersivity results in an earlier breakthrough but the shape  
29 becomes flatter.

50 Regular monitoring data are available for four drinking wells between 1995 and 2009,  
51 and the trend in BAM concentration can be compared with the results of the two modeling  
52 approaches (Fig. 5). The concentration in the four drinking wells decreases or stabilizes  
53 between 1995 and 2009, corresponding to the results of the DF tool. In contrast the EPM

1 model predicts an increasing trend between 1995 and 2009. A combination of a very low  
2 effective porosity (3%) and high dispersivity (1m) is necessary to fit the EPM model to the  
3 monitoring data. However, these parameters are effective parameters and do not correspond to  
4 physical properties. Therefore they can be obtained by calibration but their use for prediction  
5 is limited because they are expected to change from site to site, depending on physical scales  
6 and flow characteristics. Furthermore an effective porosity of 3% mimics the presence of  
7 preferential flow pathways in the equivalent porous media. It is possible to calibrate the DF  
8 tool so that the concentration levels better match the observations (lower infiltration and/or  
9 source area), but the objective is to model the presence and the decreasing concentrations  
10 observed in the drinking water wells without parameter calibration.

24 The time series data from the four drinking wells indicate that the presence of fractures is  
25 necessary to explain the decreasing trend observed in the BAM concentrations between 1995  
26 and 2009. Furthermore the DF approach corroborates with the geological and experimental  
27 knowledge collected at the site. Despite these encouraging results, earlier breakthrough or late  
28 time data would increase confidence in model results. However such data is not available.

### 48 **5.3.2 Case II – Chlorinated solvents in fractured clayey till**

49

50 At a former factory, trichloroethene (TCE) has been used extensively in the 60-70's and  
51 has led to the contamination of the saturated clayey till and (to some extent) the underlying  
52 chalk aquifer (Miljøkontrollen, 2004). No physical source has been found at the site and the  
53 period of TCE contamination is unknown, but the contaminant hotspot is located over an area  
54  
55  
56

1 of 140 m<sup>2</sup>, overlying the regional chalk aquifer, mainly in 5 meters saturated clayey till (3 to 8  
2 mbs). The main contaminant is TCE and degradation has not been observed at the site  
3 (aerobic aquifer). The average concentration in the source zone is estimated to be 30 mg/kg  
4  
5 dry soil and the source zone therefore contains about 40 kg, assuming a bulk density  $\rho_b$  of  
6  
7 1.95 kg/L. Assuming a sorption coefficient  $K_d$  of 0.6 L/kg and a porosity  $\phi$  of 0.3, the  
8  
9 retardation factor in the matrix is  $R_m = 4.9$  and the average aqueous concentration in the  
10  
11 source zone ( $C_I$ ) is 40 mg/L. The free diffusion of TCE in water is  $7.3 \times 10^{-10} \text{ m}^2 \cdot \text{s}^{-1}$  (US EPA,  
12  
13 2010a). As for the previous example, typical values are used for the fractures in the clayey till  
14  
15 with a vertical spacing of 1 m and an aperture of 25  $\mu\text{m}$ . The recharge to the regional aquifer  
16  
17 is assumed to be 100 mm/year.  
18  
19  
20  
21  
22  
23

24 Model 2 (see Fig. 2) is used to assess the leaching concentration to the regional aquifer  
25 ( $C_f$ ) and the expected concentration in the monitoring boreholes in the chalk aquifer. The  
26  
27 dilution factor ( $\text{DAF} = 9$ ) is calculated using the chalk aquifer characteristics and a mixing  
28  
29 zone depth equal to the screen length of the monitoring wells (2 m).

37 **Fig. 6.** TCE concentration in the water leaching from the source zone (left) and in the regional aquifer (right).  
38 Results from the DF (—) and EPM (— —) models. The measured concentration range in the chalk aquifer is  
39 illustrated with a grey box. The timing of observed concentrations relatively to leaching initiation is not known  
40  
41 but is between 5 and 25 years. Data from Miljøkontrollen (2006a; 2006b).  
42  
43  
44  
45  
46

47 The leaching concentration (Fig. 6, left) decreases quickly from 40 mg/L to 20 mg/L over  
48 a period of 20 years, and has a long tailing with concentration above 10 mg/L for more than  
49  
50 150 years. In contrast, an EPM model predicts a constant concentration of 40 mg/L for a  
51  
52 period of 50 years, followed by a fast decrease to less than 1 mg/L after 100 years. The  
53  
54 expected concentration in the regional aquifer is shown in Fig. 6 right, for the two approaches.  
55  
56 The concentration is expected to remain above 1 mg/L for at least 50 years. The  
57  
58  
59  
60  
61  
62  
63  
64  
65

1 concentrations at the site were measured in the underlying aquifer in three boreholes: B29  
2 where 2.7 mg/L was measured (Sept 2006); B30 where 1.9 mg/L was measured (Sept 2006);  
3  
4 and B15 with recordings of 1.5 mg/L (Dec. 2004), 1.25 mg/L (Jan 2006) and 1.2 mg/L (Sept.  
5  
6 2006). These data are shown in Fig. 6 with the grey box, as the initial leaching time is not  
7  
8 known, but results are similar to those of the DF tool after 20 to 50 years and the order of  
9  
10 magnitude of observed concentrations is well predicted by the model.  
11  
12

13  
14 In general for conceptual model 2, the leaching time is overestimated by the single  
15  
16 fracture model of this paper because the infinite matrix acts as a longer term source than  
17  
18 would be the case for a multiple fracture model (see Supplementary information, Fig. S2).  
19  
20 The mass discharge to the aquifer is greater than predicted by EPM model, and because the  
21  
22 initial concentration in the matrix is uniform and the matrix is infinite in extent, the mass  
23  
24 leaching from the fractured media eventually exceeds the initial mass in the system. This has  
25  
26 to be taken into account when assessing the risk and leaching timeframes.  
27  
28  
29  
30

### 31 **5.3.3 Case III – Contamination with benzene and MTBE**

32  
33  
34  
35 The DF tool is used to assess the risk posed by a BTEX source overlying a fractured clay  
36  
37 geology on an underlying aquifer (Danish EPA, 2003, p. 19-20). Benzene and MTBE have  
38  
39 been measured in the source zone (0.33 and 1.8 mg/L, respectively), which overlies a 6 meter-  
40  
41 thick clayey till. The regional aquifer is located under the clayey till layer. A vertical gradient  
42  
43 has been measured throughout the saturated clayey till (15%), and the modeling tool is used to  
44  
45 assess the vertical transport of MTBE and benzene through 6 meters of fractured porous  
46  
47 media. According to the redox conditions at the site (anaerobic), MTBE is assumed not to be  
48  
49 degraded and a conservative first order degradation rate is used for benzene ( $\lambda = 0.001 \text{ d}^{-1}$ ).  
50  
51 The sorption coefficient  $K_d$  for MTBE and benzene are calculated from  $K_{oc}$  values (12 and 59  
52  
53 l/kg, respectively, (US EPA, 2010b)) and an estimated organic carbon fraction  $f_{oc} = 0.01$  (-).  
54  
55 The bulk density ( $\rho_b$ ) and the porosity ( $\phi$ ) of the clay matrix are estimated to be 1.95 kg/L and

0.3, respectively. The retardation coefficient in the matrix is calculated to be  $R_m = 1.8$  and  $4.8$ , for MTBE and benzene respectively. The free diffusion of MTBE and benzene in water is  $5.6 \times 10^{-10}$  and  $6.6 \times 10^{-10} \text{ m}^2 \cdot \text{s}^{-1}$ , respectively (US EPA, 2010a).

Model 1b (see Fig. 2) is used to assess the leaching concentration to the regional aquifer ( $C_l$ ) and the expected concentration in the monitoring well in the aquifer. The dilution factor (DAF = 64) is calculated using the sand aquifer characteristics and a screen length of 2 m. An EPM model is also applied to assess the leaching concentration.

**Fig. 7.** a) MTBE concentration in leaching water ( $C_{\text{leaching}}$ ) and in underlying groundwater ( $C_{\text{GW}}$ ) (monitoring well) for the DF tool (black) and EPM model (grey). b) Benzene concentration in leaching water and in underlying groundwater (monitoring well) for the DF tool (black) and EPM model (grey). Note the break in y-axis. The arrows indicate the measured concentration levels in the monitoring well in the aquifer (MTBE, 0.73 mg/L and benzene, 0.19 mg/L). Data from Danish EPA (2003, p. 19-20).

For the conservative compound (MTBE), the DF tool predicts a breakthrough time earlier than the EPM model (2 and 35 years, respectively, for  $C_{\text{leaching}}$  above  $0.1 \mu\text{g/L}$ ), due to the fast downward pathways along the fractures. Furthermore, the transient behavior can be compared with the steady-state solution of conceptual model 1b (Eq.(6)) (solid line in Fig. 7a). It takes more than 100 years for the transient solution to reach the steady-state concentration ( $C_{\text{leaching}} = C_0 = 0.33 \text{ mg/L}$ ). The predicted concentrations in the underlying groundwater (around  $0.004 \text{ mg/L}$  for the DF tool) are below the measured concentration ( $0.73 \text{ mg/L}$ ). The Danish groundwater criteria for MTBE ( $5 \mu\text{g/L}$ , Danish EPA, 2008) is expected to be exceeded after 90 and 500 years for the EPM and DF models, respectively, if the contaminant source remains. This illustrates the importance of considering the transient behavior of vertical contaminant leaching through low permeability media.

1 For the degradable compound (benzene), the steady-state leaching concentration is 130  
2  $\mu\text{g/L}$  in the DF model and 0  $\mu\text{g/L}$  for the EPM model. This large difference is due to the fact  
3  
4 that the residence time in the clay till is very high for an EPM model (35 years), whereas  
5  
6 vertical transport along the fractures is very fast (1 day). The benzene breakthrough to the  
7  
8 aquifer is well predicted with the DF tool, however the modeled concentration is 100 times  
9  
10 lower than measured in the monitoring well (0.002 vs. 0.2 mg/L). In contrast, benzene is not  
11  
12 predicted to reach the aquifer by the EPM model. In this case study, only the DF model  
13  
14 predicts that the groundwater concentration will exceed quality criteria for benzene (1  $\mu\text{g/L}$ ,  
15  
16 Danish EPA, 2008), while the EPM model gives the incorrect result of zero aquifer  
17  
18 concentration and no resultant risk.

## 25 **6 Fracture model vs. EPM – Implication for risk assessment**

26  
27  
28 The developed DF model tool was compared for the three case studies with an equivalent  
29  
30 porous media (EPM) model, because it is generally used in common risk assessment tools. As  
31  
32 discussed in the case studies section, it is not possible to conclusively demonstrate the correct  
33  
34 simulation of observed data with DF tool (vs. EPM) because of a lack of long term data. An  
35  
36 important consideration in risk assessment in fractured media should be to ensure that any  
37  
38 uncertainty is expressed as an over- and not under-estimation of the risk. However the notion  
39  
40 of risk can be difficult to define objectively. Furthermore, for transient simulations, the notion  
41  
42 of risk depends on the time at which it is considered. In this paper, the DF and EPM models  
43  
44 are compared in terms of peak concentration and leaching time.  
45  
46  
47  
48  
49

50 For a conservative compound (Fig. 5, Fig. 6 and Fig. 7a) the main difference between the  
51  
52 two approaches is the breakthrough time, which is underestimated by the EPM model. The  
53  
54 peak concentration is the same for the two approaches with conceptual model 1b ( $C_{\text{max}} = C_0$ ),  
55  
56 while it is similar for conceptual model 1a (cf. Fig. 5). The predicted leaching time is longer  
57  
58 for the DF tool, with long tailing due to high storage capacity in the matrix (cf. Fig. 5 and Fig.  
59  
60

6). However it should be noted that the leaching time is overestimated with the developed tool due to the single fracture assumption.

For a degradable compound (Fig. 7b), the EPM model predicts a very high attenuation and the peak concentration can be several orders of magnitude lower than the results from the DF tool. The use of EPM model for degradable compounds will therefore result in an underestimation of the risk posed to the underlying aquifer and the results from the DF tool are the most conservative in this case.

## 7 Model limitations and data needs

The analytical solutions presented in this study are meant to cover the various common scenarios of contamination of fractured media when assessing the risk posed to an underlying aquifer. For use in a regulatory context, when dealing with numerous contaminated sites and data scarcity, several simplifications are necessary in order to obtain simple analytical solutions. The fracture network is simplified to the minimum by assuming a single fracture embedded in a porous matrix. The models are not suitable for highly fractured media, with small average fracture spacing ( $2B > 1-1.5$  m). Furthermore diffusion is assumed to be the dominant process in the porous matrix, so the models are applicable to low-permeability settings only (such as clayey tills).

Another limitation is the representation of microbial degradation. Several compounds (such as chlorinated solvents and pesticides) can undergo sequential degradation, where the intermediate products are also toxic and should be included in a risk assessment, as it can result in an increased risk for the groundwater (Chambon et al., 2010). This is not considered in the presented tool, but analytical solutions exist for radioactive decay chain and constant input source and could be further developed for the three conceptual models presented here (Sun and Buscheck, 2003). Furthermore the models assume uniform degradation in the matrix and fracture, whereas some studies show that degradation occur preferentially in and around

1 the high permeability zones formed by the fracture, especially when the transport of bacteria,  
2 reactants or nutrient is limited by diffusion (Hønning et al., 2007; Scheutz et al., 2010). In  
3 such cases the attenuation due to degradation will be largely overestimated by the risk  
4 assessment tool (Chambon et al., 2010). For degradation occurring only in the fracture  
5 domain, it has been shown that the attenuation is negligible (Chambon et al., 2010) and the  
6 analytical solutions for conservative compounds can then be used.  
7  
8  
9  
10  
11  
12  
13

14 Finally the choice of parameters is generally based on limited site specific data and even  
15 if the data requirements for such analytical solutions are minimal, standard values from the  
16 literature are often necessary. However specific parameters for fractured porous-media (such  
17 as fracture spacing, aperture, degradation rates) are relatively limited in the literature.

## 25 **8 Conclusions**

26  
27  
28 The DF tool provides a practical framework for assessing the risk of groundwater  
29 contamination, while considering complicating factors of transport through low-permeability  
30 fractured media. The tool includes different source geometries, which cover the typical  
31 scenarios encountered at contaminated sites situated in low-permeability settings. The  
32 comparison of the DF tool with observed data is limited by the lack of historical records  
33 documenting early breakthrough and long term leaching. The DF tool is based on geological  
34 physical parameters, and is shown to provide valuable information on the risk posed by  
35 different contamination sources to the groundwater. In contrast, the EPM approach has  
36 fundamentally different output and is not consistent with observed fracture transport  
37 mechanisms. The DF tool does not require many additional parameters and should therefore  
38 be preferred for use in risk assessment for fractured media.

## Appendix

### Development of analytical solution for model 1a

For model 1a, the boundary and initial conditions for Eq.(1) and (2) are

$$\begin{aligned}
 C_f(z, 0) &= 0 & C_m(x, z, 0) &= C_1 \\
 C_f(0, t) &= \begin{cases} C_0 & t < a \\ 0 & t > a \end{cases} & C_m(b, z, t) &= C_f(z, t) \\
 C_f(\infty, t) &= 0 & C_m(\infty, z, t) &= 0
 \end{aligned} \tag{A.1}$$

Where  $C_0$  is the constant concentration of the source released during  $t = 0$  and  $t = a$  at  $z = 0$ .

Applying the Laplace transform to Eq.(2) for the matrix gives:

$$p\bar{C}_m - \frac{D_m}{R_m} \frac{\partial^2 \bar{C}_m}{\partial z^2} + \frac{\lambda}{R_m} \bar{C}_m = 0 \tag{A.2}$$

The solution to this second-order differential equation is (using the boundary condition given by Eq.(A.1)):

$$\bar{C}_m = \bar{C}_f \exp\left(-G \sqrt{\frac{\lambda}{R_m}} (x - b)\right) \tag{A.3}$$

The gradient of  $\bar{C}_m$  at the interface  $x = b$  is then

$$\left. \frac{\partial \bar{C}_m}{\partial x} \right|_{x=b} = -\bar{C}_f G \sqrt{p + \frac{\lambda}{R_m}} \tag{A.4}$$

Applying Laplace transform to Eq.(1) for a fracture, and after substituting Eq.(A.4) for the interface gradient gives:

$$\frac{\partial \bar{C}_f}{\partial z} - \frac{R_f}{v_f} \left( p + \frac{\lambda}{R_f} + \frac{\sqrt{p + \lambda/R_m}}{A} \right) \bar{C}_f = 0 \tag{A.5}$$

The solution to Eq.(A.5) is of the form:

$$\bar{C}_f = C_3 \exp\left(-\frac{\lambda z}{v_f}\right) \exp(-pH) \exp\left(-\frac{H \sqrt{p + \lambda/R_m}}{A}\right) \tag{A.6}$$

$C_3$  can be determined by using the Laplace transform of boundary condition defined in

Eq.(A.1):

$$\overline{C_f}(0, p) = C_3 = C_0 \frac{1 - \exp(-ap)}{p} \quad (\text{A.7})$$

The concentration in the fracture  $C_f$  can be expressed in term of the inverse transform  $L^{-1}$  as:

$$\frac{C_f}{C_0} = \exp\left(-\frac{\lambda z}{v_f}\right) \left[ \begin{array}{l} L^{-1} \left\{ \frac{1}{p} \exp(-pH) \exp\left(-\frac{H\sqrt{p + \lambda/R_m}}{A}\right) \right\} \\ -L^{-1} \left\{ \frac{1}{p} \exp(-p(H+a)) \exp\left(-\frac{H\sqrt{p + \lambda/R_m}}{A}\right) \right\} \end{array} \right] \quad (\text{A.8})$$

To evaluate the inverse transform we use the following identity from Tang et al. (1981):

$$L^{-1}\left(\frac{1}{p} \exp(-\tau p) \exp(-k\sqrt{p+\omega})\right) = \begin{cases} \frac{1}{2} \left[ \exp(-k\sqrt{\omega}) \operatorname{erfc}\left(\frac{k}{2\sqrt{t-\tau}} - \sqrt{\omega}\sqrt{t-\tau}\right) \right. \\ \left. + \exp(k\sqrt{\omega}) \operatorname{erfc}\left(\frac{k}{2\sqrt{t-\tau}} + \sqrt{\omega}\sqrt{t-\tau}\right) \right] & t > \tau \\ 0 & t < \tau \end{cases} \quad (\text{A.9})$$

Which gives the solution for the concentration in the fracture Eq.(4) and in the matrix Eq.(5) shown in the main text.

## Development of analytical solution for model 2

For model 2, the boundary and initial conditions for Eq.(1) and (2) are:

$$\begin{aligned} C_f(z, 0) &= C_1 & C_m(x, z, 0) &= C_1 \\ C_f(0, t) &= 0 & C_m(b, z, t) &= C_f(z, t) \\ C_f(\infty, t) &= C_1 \exp\left(-\frac{\lambda}{R_f} t\right) & C_m(\infty, z, t) &= C_1 \exp\left(-\frac{\lambda}{R_m} t\right) \end{aligned} \quad (\text{A.10})$$

Where  $C_1$  is the uniform concentration in the fractured media.

The Laplace transform is defined by:

$$f'(t) = pF(p) - f(t=0) \quad (\text{A.11})$$

So the Laplace transform of Eq.(2) is:

$$p\bar{C}_m - C_1 - \frac{D_m}{R_m} \frac{\partial^2 \bar{C}_m}{\partial z^2} + \frac{\lambda}{R_m} \bar{C}_m = 0 \quad (\text{A.12})$$

The solution to this second-order differential equation is of the form:

$$\bar{C}_m = C_1 \exp\left(-G\sqrt{p + \lambda/R_m}(x-b)\right) + \frac{C_1}{p + \lambda/R_m} \quad (\text{A.13})$$

$$G = \sqrt{R_m/D_m}$$

$C_1$  can be determined by using the Laplace transform of the boundary condition in Eq.(A.10):

$$\bar{C}_m(b, z, p) = \bar{C}_f = C_1 + \frac{C_1}{p + \lambda/R_m} \quad (\text{A.14})$$

$$C_1 = \bar{C}_f - \frac{C_1}{p + \lambda/R_m}$$

Eq.(A.13) then becomes:

$$\bar{C}_m = \bar{C}_f \exp\left(-G\sqrt{p + \lambda/R_m}(x-b)\right) + \frac{C_1}{p + \lambda/R_m} \left(1 - \exp\left(-G\sqrt{p + \lambda/R_m}(x-b)\right)\right) \quad (\text{A.15})$$

The gradient of  $\bar{C}_m$  at the interface  $x = b$  is then

$$\left. \frac{\partial \bar{C}_m}{\partial x} \right|_{x=b} = -\bar{C}_f G \sqrt{p + \lambda/R_m} + \frac{C_1}{\sqrt{p + \lambda/R_m}} G \quad (\text{A.16})$$

Applying Laplace transform to Eq.(1) for a fracture, and after substituting Eq.(A.16) for the interface gradient gives:

$$\frac{\partial \bar{C}_f}{\partial z} + \frac{R_f}{v_f} \left( p + \lambda/R_f + \frac{\sqrt{p + \lambda/R_m}}{A} \right) \bar{C}_f = C_1 \frac{R_f}{v_f} \left( 1 + \frac{1}{A\sqrt{\lambda/R_m}} \right) \quad (\text{A.17})$$

The solution to Eq.(A.17) is of the form:

$$\bar{C}_f = C_2 \left( \begin{array}{c} \exp\left(-\frac{\lambda z}{v_f}\right) \exp(-pH) \\ \exp\left(-\frac{H}{A} \sqrt{p + \lambda/R_m}\right) \end{array} \right) + C_1 \frac{A \sqrt{p + \lambda/R_m} + 1}{\sqrt{p + \lambda/R_m}} \frac{1}{A \left( p + \lambda/R_f \right) + \sqrt{p + \lambda/R_m}} \quad (\text{A.18})$$

The following simplification has to be made in the second term of Eq.(A.18):

$$\lambda/R_f \approx \lambda/R_m \quad (\text{A.19})$$

This simplification may over- or underestimate the effective degradation rate in the fracture but the errors introduced by this approximations are very small for most cases.

Substituting Eq.(A.19) into Eq.(A.18) gives:

$$\bar{C}_f = C_2 \left( \exp\left(-\frac{\lambda z}{v_f}\right) \exp(-pH) \exp\left(-\frac{H}{A} \sqrt{p + \lambda/R_m}\right) \right) + \frac{C_1}{\left( p + \lambda/R_m \right)} \quad (\text{A.20})$$

$C_2$  can be determined by using the Laplace transform of boundary condition defined in Eq.(A.10) and Eq.(A.20) becomes:

$$\bar{C}_f = \frac{C_1}{\left( p + \lambda/R_m \right)} \left( 1 - \left( \exp\left(-\frac{\lambda z}{v_f}\right) \exp(-pH) \exp\left(-\frac{H}{A} \sqrt{p + \lambda/R_m}\right) \right) \right) \quad (\text{A.21})$$

The concentration in the fracture  $C_f$  can be expressed in term of the inverse transform  $L^{-1}$  as:

$$C_f = C_1 \exp\left(-\lambda/R_m t\right) - \exp\left(-\lambda z/v_f\right) \cdot L^{-1} \left( \frac{C_1}{\left( p + \lambda/R_m \right)} \exp(-pH) \exp\left(-\frac{H}{A} \sqrt{p + \lambda/R_m}\right) \right) \quad (\text{A.22})$$

To evaluate the inverse transform we use the following identities:

$$L^{-1} \left( \frac{\exp(-kp^{1/2})}{p} \right) = \text{erfc} \left( \frac{k}{2t^{1/2}} \right)$$

$$L^{-1} (F(p + \omega)) = \exp(-\omega t) L^{-1} (F(p)) \quad (\text{A.23})$$

$$L^{-1} (\exp(-\tau p) F(p)) = \begin{array}{ll} f(t - \tau) & t > \tau \\ = 0 & t < \tau \end{array}$$

A fourth identity can be obtained by combining the three in Eq.(A.23):

$$L^{-1} \left( \exp(-\tau p) \frac{\exp(-k(p+\omega)^{1/2})}{p+\omega} \right) = \exp(-\omega(t-\tau)) \operatorname{erfc} \left( \frac{k}{2(t-\tau)^{1/2}} \right) \quad (\text{A.24})$$

Using Eq.(A.24) we can express the inverse transform in Eq.(A.22) as:

$$L^{-1} \left( \frac{C_1}{\left(p + \frac{\lambda}{R_m}\right)} \exp(-pH) \exp\left(-\frac{H}{A} \sqrt{p + \frac{\lambda}{R_m}}\right) \right) = C_1 \begin{cases} \exp\left(-\frac{\lambda}{R_m}(t-H)\right) \\ \cdot \operatorname{erfc}\left(\frac{H}{2A(t-H)^{1/2}}\right) \end{cases} \quad \begin{matrix} t > H \\ \\ t < H \end{matrix} \quad (\text{A.25})$$

$$= 0 \quad t < H$$

Substituting Eq.(A.25) into Eq.(A.22), we obtain

$$\frac{C_f}{C_1} = \exp\left(-\frac{\lambda}{R_m} t\right) - \left( \exp\left(-\frac{\lambda z}{v_f}\right) \exp\left(-\frac{\lambda}{R_m} T'^2\right) \operatorname{erfc}\left(\frac{H}{2AT'}\right) \right) \quad T' > 0 \quad (\text{A.26})$$

$$\frac{C_f}{C_1} = \exp\left(-\frac{\lambda}{R_m} t\right) \quad T' < 0$$

To find the solution for the porous matrix Eq.(A.21), and Eq.(A.15) are combined to obtain

$$\bar{C}_m = \frac{C_1}{\left(p + \frac{\lambda}{R_m}\right)} \left( 1 - \exp\left(-\frac{\lambda z}{v_f}\right) \exp(-pH) \exp\left(-W \sqrt{p + \frac{\lambda}{R_m}}\right) \right) \quad (\text{A.27})$$

$$W = \frac{H}{A} + \sqrt{\frac{R_m}{D_m}} (x-b)$$

By using Eq.(A.25), the inverse of Eq.(A.27) is obtained:

$$\frac{C_m}{C_1} = \exp\left(-\frac{\lambda}{R_m} t\right) - \left( \exp\left(-\frac{\lambda z}{v_f}\right) \exp\left(-\frac{\lambda}{R_m} T'^2\right) \operatorname{erfc}\left(\frac{W}{2T'}\right) \right) T' > 0 \quad (\text{A.28})$$

$$\frac{C_m}{C_1} = \exp\left(-\frac{\lambda}{R_m} t\right) \quad T' < 0$$

## 1 SUPPLEMENTARY INFORMATION

2 **Single fracture simplification**

3 In this section the use of the single fracture model to simplify a parallel fractures system is  
 4 assessed. In the context of risk assessment a conservative approach (i.e overestimation of the  
 5 risk) is typically preferred. The parameters were chosen to maximize the effects of the  
 6 assumption of single fracture (high diffusion coefficient and low retardation factor) (see Table  
 7 S1). The numerical model developed in Chambon et al. (2010) is used to simulate the parallel  
 8 fracture system.

9 **Table S1**

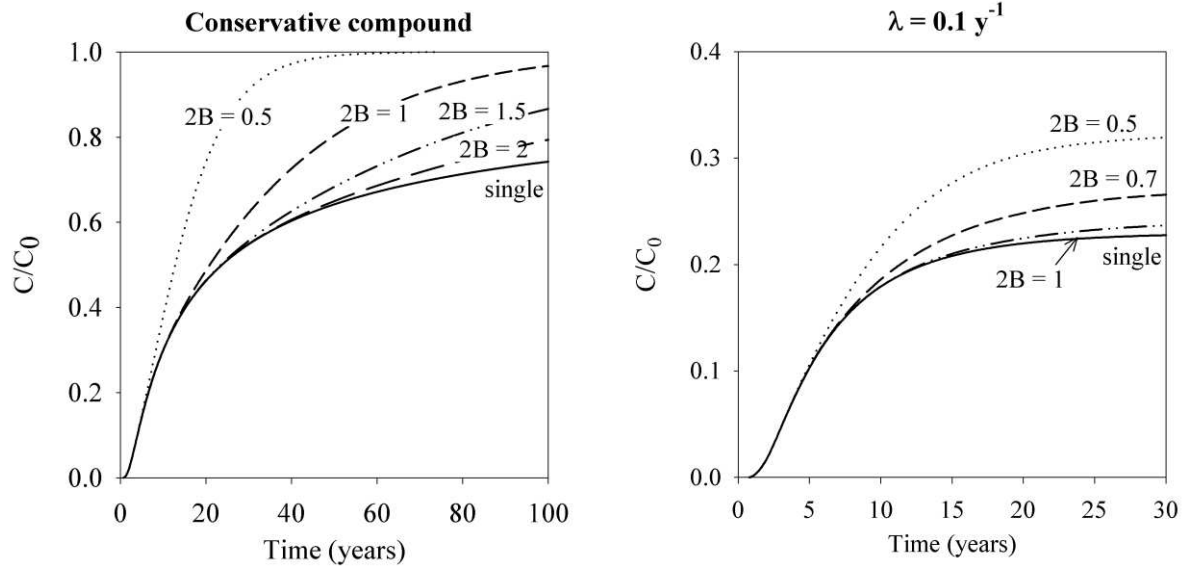

10 Parameters used in comparison between single and parallel fractures

<b>Parameters</b>	<b>Single vs. parallel fractures</b>
Fracture spacing $2B$ (m)	variable
Fracture aperture $2b$ ( $\mu\text{m}$ )	25
Matrix porosity $\phi$ (-)	0.3
Velocity in fracture $v_f$ (m/y)	2000
Diffusion coefficient in matrix $D_m$ ( $\text{m}^2/\text{y}$ )	$6 \times 10^{-3}$
Retardation factor $R_m = R_f$	1
Degradation rate $\lambda$ ( $\text{y}^{-1}$ )	0 – 0.1

11

12 The effects of the simplification are illustrated for model 1b (constant source), as the  
 13 effects for model 1a are lower. The simplification results in underestimating concentration in  
 14 the fracture for model 1b, because the storage capacity of the matrix is not finite and the  
 15 attenuation due to diffusion into the matrix is then higher than for the case of parallel  
 16 fractures. However the difference between the two systems decreases with increasing fracture  
 17 spacing and degradation rate. This is illustrated in the example in Fig. S1 using the parameters  
 18 from Table S1. For a conservative compound, the single fracture model is close to the parallel  
 19 fractures system for spacing larger than 2 meters, whereas this value decreases to 1 meter for  
 20 a slow degradable compound ( $\lambda = 0.1 \text{ y}^{-1}$ ).

21

1  
 2 **Fig. S1.** Breakthrough curves of model 1b at  $z = 5$  m for a conservative ( $\lambda = 0$ ) and a degradable compound ( $\lambda =$   
 3  $0.1 \text{ y}^{-1}$ ), and various fracture spacings. Note different time and concentration scales. Parameters from Table S1.

4

5 For conceptual model 2 the effects of the single fracture assumption are illustrated in  
 6 Fig. S2, which compares the leaching concentration from the risk assessment tool (single  
 7 fracture) with the numerical solution for various fracture spacings. As for model 1b, the single  
 8 fracture model is close to the parallel fractures system for spacing larger than 2 meters,  
 9 whereas this value decreases to 0.5 meter for a slow degradable compound ( $\lambda = 0.1 \text{ y}^{-1}$ ). The  
 10 discrepancy between the two systems is due to the continuous supply of contaminant from the  
 11 infinite matrix in the case of single fracture. The assumption of a single fracture embedded in  
 12 a semi-infinite matrix results in an overestimation of the contaminant mass discharge to the  
 13 aquifer, which can then be higher than the initial mass in the system.

14

1

2 **Fig. S2.** Breakthrough curves of model 2 at  $z = 5$  m for a conservative ( $\lambda = 0$ ) and a degradable compound ( $\lambda =$   
 3  $0.1 \text{ y}^{-1}$ ), and various fracture spacings. Note different time scales. Parameters from Table S1.
