Keywords: Random periodic packing, Curved fibers, Fiber orientation

ABSTRACT

Numerical models generating actual fiber architecture by including parameters such as the fiber geometry and arrangement are a powerful tool to explore the relation between the fiber architecture and mechanical properties. The generation of virtual architectures of fibrous materials is the first step toward the computation of their physical properties. In this work, a realistic 3D model is developed to describe the architecture of a complex fiber structure. The domain of application of the model could include natural fibers composites, wood fibers materials, papers, mineral and steel wools and polymer networks. The model takes into account the complex geometry of the fiber arrangement in which a fiber can be modeled with a certain degree of bending while keeping a main fiber orientation. The model is built in two steps. First, fibers are generated as a chain of overlapping spheres or as a chain of overlapping spherocylinders. At the end of the first step, a system of overlapping fibers is obtained. In order to obtain a hard-core configuration where fibers cannot overlap other fibers, we use an iterative method called the force-biased algorithm. It applies virtual forces on each point of the fiber: a repulsion force to suppress the overlap between two fibers and a bending and stretching force to ensure that the fiber structure is kept unchanged. The model can be used as the geometrical basis for further finite-element modelling.

1 INTRODUCTION

The generation of a packing of objects in a space can either be designated as a soft-core or hard-core process. In a soft-core model, the overlap of the packed object is allowed which is not realistic from a physical point of view. However the simplicity of implementation of those processes has made it a quite popular tool for the microstructure generation of complex materials. One of the first soft-core processes generating a packing of fibers was introduced by Matheron [1]. It made use of dilated Poisson lines to create straight infinite cylinders [1]. Later, lines were generated by a Poisson process in [2–5] to model respectively the microstructure of a nonwoven material, the gas diffusion layer of proton exchange membrane fuel cells and the fiber structure of thermal and acoustic materials. Soft-core models were developed further to consider fibers with a more complex geometry. For example, to model curved fiber system, several soft-core processes include bending of the fibers through random walks whose direction are controlled by von Mises-Fischer distribution [6, 7]. Others have introduced bending of the fibers by interpolating points with B-splines [8, 9].

The random sequential adsorption (RSA) model is probably the most commonly used method to construct hard-core systems because its principle is relatively simple even though its implementation can be a bit tricky for objects with a complex geometry. The RSA scheme iteratively generates objects and tries to place them in such a way that they do not intersect. Initially created for the packing of
spheres, the process was then applied on cylinders by Feder [10]. Bezrukov and Stoyan proposed an algorithm for the generation of random packing of ellipsoids of revolution [11]. Contacts between ellipsoids are detected and a force biased algorithm is applied to translate and rotate the particles that overlap. Both approaches achieve relatively low volume fraction (10 – 15 % for isotropic orientation with a fiber aspect ratio of 10). Recently, Naddeo et al. used an RSA based microstructure generation method with fibers shaped as cylinders but very little details on the overlap detection was provided [12]. On the other hand, in [13], the implementation of the contact detection of two cylinders is given. The problem of the RSA based method is that for fibers with an isotropic orientation distribution and high aspect ratio, only low volume fractions can be achieved as a jamming limit is reached when no new positions can be found. Modifications of the RSA algorithm can be made so that when a fiber position is rejected because it overlaps another fiber with a certain distance, a translation of this distance is applied to the fiber. Using this algorithm, microstructures with volume fractions up to 38 and 29% and randomly oriented fibers with aspect ratios of 10 and 30, respectively, were generated [14].

Another type of model based on the deposition of straight fibers can achieve hard-core configurations [15]. In that model, fibers are deposited in an iterative manner from the top of the cell and whenever they enter in contact with another fiber, they stop their falls. This approach gives high fiber volume fraction, but the fiber orientation is limited to the plane. The deposition technique is widely used for paper-like materials where the assumption of an in-plane fiber orientation distribution is quite realistic [16–18]. The fiber bending model was also included in [19]. When an overlap is detected, fibers are bent to accommodate the intersection with other fibers. Straight fibers are modelled as convex prism with two dodecagon end-faces while several convex irregular polyhedral are used in case of curved fibers. Wang et al. modeled non-woven fiber-webs by a similar deposition algorithm where the orientation was limited to a plane [20].

Some other hard-core models took inspiration in molecular dynamics simulations. For example, Ghosssein et al. used an event-driven molecular dynamics algorithm to generate spheres and ellipsoids with a very high aspect ratio (i.e.>10) in a hard-core packing configuration [21, 22]. Recently, Altendorf et al. presented a model combining some of the ideas discussed previously [23]. Firstly, bended fibers are modelled as ball chains by a random walk [24]. Secondly, similar to Wirjadi [6] and Karkkainen et al. [7] the orientation distribution can be controlled in spite of the bending. Thirdly, the force-biased approach is applied for sphere packing [25] and [11] and fourthly, the design of energies in molecular dynamics is used to define the forces [25]. It produces a random hard-core fiber model with a controllable bending and high volume fraction. The level of bending is controlled by two parameters in the multivariate von Mises Fisher distribution. As mentioned earlier, the fibers are represented as chains of spheres with defined centers and radii. The spheres are connected through random walk paths. This first step gives a soft-core system of bending fibers. To produce a hard-core configuration, a force biased approach is used. Two kinds of forces are applied to the sphere centers: repulsion and recover forces. The repulsion force prevents the overlap of fibers and the recover force maintains the sphere chain structure. Gaiselmann et al. also represented the fibers by a chain of spheres but generated the fibers midpoints with a Poisson point process and the fibers by random 3D polygonal tracks [26]. The overlap of the fibers was suppressed using a force-biased algorithm as well [25].

In the present work, a modified version of the algorithm from Altendorf et al. [23] is implemented. The modification includes the use of a chain of sphero-cylinders for the fiber model, the possibility of modeling the fiber bending using spline interpolation and the introduction of more realistic forces for the transformation into a non-overlapping fiber network.

2 GENERATION OF A SOFT-CORE FIBERS NETWORK

2.1 Fiber model

2.1.1 Chain of spheres
The first model studied in this work is the one adopted from [23, 27] where a fiber is modelled as a chain of overlapping spheres. The coordinates of the first sphere center of the chain are generated according to a uniform law in the intervals \([0 - x_{\text{max}}], [0 - y_{\text{max}}]\) and \([0 - z_{\text{max}}]\) where \(x_{\text{max}}, y_{\text{max}}\) and \(z_{\text{max}}\) are the length of the sides of the observation cell chosen for the generation. The coordinates of a point \(i \in \mathbb{N} \setminus \{0\}\) representing the center of a sphere belonging to the fiber are generated iteratively from the coordinates of their previous neighbor \(x_{i-1}\):

\[
x_i = x_{i-1} + \mu_i \cdot \frac{r_i}{2}
\]

\(r_i\) and \(\mu_i\) are respectively the fiber radius and the direction of the fiber at the point \(i\). A realization of a fiber is shown in the figure below (Fig. 1).

\[\text{Figure 1: Fiber modelled as a chain of spheres}\]

### 2.1.2 Chain of sphero-cylinder

A new discretization is proposed here where the fiber is modelled as a chain of overlapping sphero-cylinders. The generation process is similar to the one proposed in section 2.1.1. The only difference is the length of the step between two points. The first spherical part of the sphero-cylinder overlaps with the spherical part of the previous sphero-cylinder. If \(\mu_i\) designates the direction, \(l_i\) the height of the cylinder part and \(x_{i-1}\) the position of its previous neighbour, then the position of the point \(i\) is:

\[
x_i = x_{i-1} + \mu_i \cdot l_i
\]

The geometry of the sphero-cylinder and a fiber modelled by a walk of points obtained using the sphero-cylinder model are represented in the figure below (Fig. 2).

\[\text{Figure 2: Fiber modelled as a chain of sphero-cylinders}\]
2.2 Models for the fiber orientation

2.2.1 Main fiber orientation

The distribution proposed in [2] was chosen to define the orientation of the fibers. The density associated to this distribution is a function $p_{\beta}(\theta, \varphi)$ of elevation $\theta \in [0, \pi)$ and azimuth $\varphi \in [0, \pi)$:

$$p_{\beta}(\theta, \varphi) = \frac{1}{4\pi (1 + (\beta^2 - 1) \cos \theta)^{3/2}}$$

$\beta \in \mathbb{R} \setminus \{0\}$ is the anisotropy parameter. We can notice that the distribution is independent from $\varphi$.

The case $\beta = 1$ describes an isotropic fiber system and results in the uniform distribution on the sphere. For increasing $\beta$ the fibers tend to be more and more parallel to the xy-plane. For $\beta \to 0$, the distribution concentrates around the z-axis.

To sample directions selected from the distribution, the inverse cumulative distribution $G(\theta)$ is needed. Indeed, if $u$ is a uniform variable on $[0, 1]$, then $G^{-1}(u)$ follows the distribution given by $G$.

The cumulative distribution $G(\theta)$ is given by:

$$G(\theta) = \frac{1}{2} - \frac{\beta}{2\sqrt{\cos^{-2} \theta + (\beta^2 - 1)}}$$

And the inverse of $G(\theta)$ is:

$$G^{-1}(x) = \cos^{-1}\left(\frac{x}{\sqrt{x^2 - \beta x^2 + \beta^2}}\right)$$

The following procedure is applied:

1) $x_1$ and $x_2$ are sampled from a uniform distribution in $(0,1)$
2) Find $\theta$ such that $x_1 = G(\theta): \theta = G^{-1}(x_1)$
3) Find $\varphi$ such that $x_2 = F(\varphi): \varphi = 2\pi x_2$

Figure 3: Angle definition and probability density function for the $\beta$ distribution with $\beta = 10$ and $\beta = 0.1$
2.2.2 Fiber bending using von-Mises Fischer distribution

The von-Mises Fischer (vMF) distribution is a well-known distribution used to describe the orientation of objects with a preferred direction and a reliability parameter. The probability density element of a vMF distribution for a vector \( u \) with a preferred direction vector \( \mu \) and a reliability parameter \( \kappa \) is:

\[
f(u|\mu, \kappa) = \frac{\kappa}{2\pi(e^\kappa - e^{-\kappa})} e^{\kappa \mu^T u}
\] (6)

We present in table 1 the algorithm for sampling a vector from a vMF distribution. Details of the implementation can be found in [28, 29].

Kärkkäinen et al. and later Altendorf and Jeulin have extended the univariate von Mises-Fischer distribution to a multivariate one in order to make use of two preferred directions and two reliability parameters [7, 23]. One of the preferred directions is the main fiber orientation while the other is set to be the direction of the previous element of the fiber.

The probability density function of a bivariate von Mises-Fischer distribution for a sampled direction \( u \) with preferred directions \( \mu_1 \) and \( \mu_2 \) and corresponding reliability parameters \( \kappa_1 \) and \( \kappa_2 \) is:

\[
f(u|\mu_1, \kappa_1, \mu_2, \kappa_2) = \frac{|\kappa_1 \mu_1 + \kappa_2 \mu_2|}{2\pi(e^{|\kappa_1 \mu_1 + \kappa_2 \mu_2|} - e^{-|\kappa_1 \mu_1 + \kappa_2 \mu_2|})} e^{(\kappa_1 \mu_1^T u + \kappa_2 \mu_2^T u)}
\] (7)

To generate random directions following a bivariate von Mises-Fischer distribution, we use the same algorithm as presented before as the bivariate function can be written as a classical von Mises-Fischer distribution by setting:
$$\boldsymbol{\kappa} = |\kappa_1 \boldsymbol{\mu}_1 + \kappa_2 \boldsymbol{\mu}_2| \text{ and } \boldsymbol{\mu} = \frac{\kappa_1 \boldsymbol{\mu}_1 + \kappa_2 \boldsymbol{\mu}_2}{\kappa}$$  \hspace{1cm} (8)

Table 1: Sampling a vector from a vMF distribution

Algorithm 1

A. Define a vector \( \boldsymbol{w}_k \) with mean direction \( \boldsymbol{\mu} = (0, 0, 1)^T \) distributed according to a vMF distribution

B. \( \boldsymbol{w}_k = (\sqrt{1 - W^2}, W, V) \) where \( V \) and \( W \) are independent random variables, \( V \in \mathbb{R}^2 \) is a uniformly distributed vector on the unit circle, and \( W \in [-1; 1] \) follow the density:

\[
f(v|\kappa) = \kappa \left( e^\kappa - e^{-\kappa} \right) e^{\kappa v} \]

1. Compute the cumulative function of \( f \):

\[
F(x) = \kappa \left( e^\kappa - e^{-\kappa} \right) \left( e^{\kappa x} - e^{-\kappa} \right) \]

2. Compute the inverse of \( F \):

\[
F^{-1}(y) = \frac{1}{\kappa} \log \left( e^{-\kappa} + \kappa e^{\kappa - e^{-\kappa}} y \right) \]

3. Draw a scalar \( y \) from a uniform distribution in the interval \((0, 1)\)

4. Compute \( W \):

\[
F^{-1}(y) = W \]

5. Draw a variable \( V \) from a uniform distribution on the unit circle

6. Compute \( \boldsymbol{w}_k = (\sqrt{1 - W^2}, V, W)^T \)

C. Apply a rotation matrix to generate a vector with a mean direction other than \((0, 0, 1)^T\)

2.2.3 Bending introduced by splines

In this approach, a line is generated in 3D using the orientation distribution defined in 2.2.1 and curvature points are added around this line by adding a deviation parameter to points belonging to the line.

\[
\boldsymbol{p}_{2i} = \boldsymbol{p}_{1i} + \Delta \boldsymbol{s} = \begin{pmatrix} x_{1i} \\ y_{1i} \\ z_{1i} \end{pmatrix} + \begin{pmatrix} \Delta s_x \\ \Delta s_y \\ \Delta s_z \end{pmatrix} \]

(9)

The points are then used as control points to generate a cubic spline. The degree of curvature and tortuosity of a fiber can be controlled by adjusting the number of points that deviates from the line and the deviation parameter, \( \Delta \boldsymbol{s} \).

2.3 Generation of a system with overlapping fibers

A system with overlapping fibers is created using either the chain of spheres or chain of spherocylinders approach. The bending and orientation of the chain is described by the distribution described in section 2.2. The algorithm for the generation of a system of overlapping fibers is given in table 2.

Table 2: Generation of a system of overlapping fibers

Algorithm 2:

A. Ask for inputs for the fiber main orientation \( (\beta) \), the fibre bending \( (\kappa_1, \boldsymbol{\mu}_1, \kappa_2, \boldsymbol{\mu}_2 \text{ or } \Delta \boldsymbol{s}) \), the fibre aspect ratio, the fibre volume fraction \( (V_f) \) and the size of the cell

B. Initialize variables (current volume \( V \), array containing the future fibre data points)

C. \textbf{WHILE} \( ||V - V_f|| \leq \text{small number} \)

1. \textbf{WHILE} \( \|\text{desired aspect ratio} - \text{current aspect ratio}\| \leq \text{small number} \)

   i. \( x_i = x_{i-1} + \mu_1 \cdot l_i \)

2. \textbf{END WHILE}

3. \textbf{IF} points exits through a face

   i. Create a periodic images

   ii. Delete element completely outside of the cell

4. \textbf{END IF}

D. \textbf{END WHILE}
At the end of this step, a periodic system with overlapping fibers is obtained with controlled orientation, bending and aspect ratio of the fibers.

3 GENERATION OF A HARD-CORE FIBRE NETWORK

To transform the overlapping system of fibers into a hard-core one, we use the force-biased algorithm first introduced by Moscinski et al. for the packing of hard spheres [25]. Virtual forces are applied on overlapping spheres until the overlap is completely prevented. Later, Altendorf and Jeulin extended the force-biased algorithm to fiber structure and added two additional forces that ensure that the fiber stretching and bending is constrained as well [23]. In this work, the expressions for the forces are expressed as a function of the material properties. The forces are applied by small increment until the total energy of the system reaches a minimum threshold level.

3.1 Repulsion forces

The force needed to repulse two objects overlapping is inspired from the Hertz contact between two hard surfaces where the overlap is treated as the deformation.

\[ F_{\text{repulsion}} = K_r \left( \frac{r_1 r_2}{r_1 + r_2} \right) \delta^{3/2} \]  

(10)

The algorithm for the implementation of the repulsion force is presented in table 3.

For a fast implementation of the repulsion force, the search of candidate points that are susceptible to overlap is optimized by using a near neighbor list [30]. The cell containing the fibers is divided into smaller sub-cells. The neighbors of a point are searched in the cell where the point belongs as well as the adjacent cells.

3.2 Bending and tension forces

To ensure that the fiber keeps its structure while being under the action of the repulsion forces, two forces are introduced that constraint the relative motion of the elements of the fibers. The first one is limiting the stretching of the fiber axis. It acts like a spring with a constant \( K_S \) and is a function of the elongation:

\[ F_{\text{stretching}} = \frac{K_S}{l_0} \left( \frac{l_i - l_0}{l_0} \right) \]  

(10)

where \( l_0 \) is the initial distance between two elements (spheres or sphero-cylinders) and \( l_i \) is the current
distance after the application of forces. The forces are applied at the centers of the spherical parts of the spherocylinder or at the centers of the spheres depending on the elements chosen for the discretization of the fiber.

Under tensile load, the strain and the stress can be expressed as:

$$\varepsilon = \frac{l_0 - l_i}{l_0} \quad \text{and} \quad \sigma = \frac{F}{S} = \frac{K_S}{l_0 \pi r^2} \left( \frac{l_0 - l_i}{l_0} \right)$$  \hspace{1cm} (11)

By analogy with Hooke’s law, we identify the spring constant $K_S$ as:

$$K_S = E F l_0 \pi r^2$$  \hspace{1cm} (12)

The bending of the three consecutives elements of a fiber is also constrained by another force acting like a torsional spring with a constant $K_B$:

$$F_{\text{bending}} = K_B (\theta_i - \theta_0)$$  \hspace{1cm} (13)

where $\theta_0$ the initial angles between three consecutives points and $\theta_i$ the current angle. A simple system with three consecutive points $(i,j,k)$ that can be either the centers of overlapping spheres or the centers of the spherical parts of the spherocylinders is displayed in the figure below (Fig. 5).

![Figure 5: Representation of the system considered for the application of the forces](image)

We also seek to express the constant $K_B$ as a material parameter. Consider a fiber discretized in $N$ elements (spheres or spherocylinders) clamped in one end and loaded with a force $F$ in the other end. Assuming that the work in tension/compression is negligible, we show that the potential energy $E$ is:

$$E = \sum_{i=1}^{N-2} \left( \frac{1}{2} K_B (\theta_1 - \pi)^2 \right) - F\delta$$  \hspace{1cm} (14)

where $\delta$ is the deflection (Fig. 6).

We assume small strains and expressed the deflection as the sum of the displacement as a function of the current angles $\theta_i$:

$$\frac{x_i}{l_0} \approx \sin(\pi - \theta_i) \approx \pi - \theta_i \Rightarrow \delta = \sum_{i=1}^{N-2} (N - i - 1) (\pi - \theta_i)$$  \hspace{1cm} (15)

The beam is in equilibrium when the energy reaches a minimal value. Thus we derive the energy and solve $\theta_i$ for the equation $\frac{dE}{d\theta_i} = 0$
\[ \frac{\partial E}{\partial \theta_i} = K_B(\theta_i - \pi) + F_{l0}(N - i - 1) = 0 \iff \pi - \theta_i = \frac{F_{l0}}{K_B}(N - i - 1) \quad (16) \]

Replacing \((\theta_0 - \theta_i)\) in equ. (13) and using the expression of the sum of squares:

\[ \delta = \sum_{i=1}^{N-2} \frac{F_{l0}}{K_B} \cdot (N - i - 1)(N - i - 1) = \frac{F_{l0}}{6K_B}(N - 2)(N - 1)(2N - 3) \quad (17) \]

Normalizing with the diameter \(D\) of the fibre:

\[ \frac{\delta}{D} = \frac{F}{3E_l D^3} \cdot \left( \frac{D^2}{K_B l_0} \right) \left( 1 - \frac{l_0}{L} \right) \left( 1 - \frac{l_0}{2L} \right) \quad (18) \]

By analogy with the beam theory, we obtain an expression for the bending constant depending on material parameters:

\[ \frac{\delta}{D} = \frac{FD^2}{3E_l l_0^3} \cdot \left( \frac{D^2}{K_B l_0} \right) \left( 1 - \frac{l_0}{L} \right) \left( 1 - \frac{l_0}{2L} \right) \Rightarrow K_B = \frac{E_l l_0}{l_0} \left( 1 - \frac{l_0}{L} \right) \left( 1 - \frac{l_0}{2L} \right) \quad (19) \]

And if the length of the elements is negligible compared to the length of the fiber, we obtain:

\[ K_B \approx \frac{E_l l_0}{l_0} \quad (20) \]

**Figure 6**: bending of a discretized fiber

### 3.3 Examples of hard-core fibers network

Figure 7 shows the realization of two hard-core fibers networks. Their main characteristics are defined in table 4. We control the fiber radius distribution by drawing the values from a lognormal law. By adjusting the value of the scale parameter \(\sigma\) of the lognormal law, the spread of the distribution can be tuned. Based on the radius and the aspect ratio we calculate the total length of the fiber and the number of discretization points for the fiber model.

4 DISCUSSION & CONCLUSION

We present here a modification of the algorithm originally proposed by Altendorf and Jeulin for the generation of a system of hard-core fibers [23]. In the modified algorithm, the fiber is modeled as a chain of sphero-cylinders rather than a chain of spheres. This implementation reduces the computational effort for the transformation of the overlapping system into a non-overlapping one as fewer points are considered when applying the forces. The bending of the fibers can be controlled using either a multivariate von Mises-Fischer distribution or a cubic b-spline interpolation. A near-neighbor list is built to determine which points are susceptible to overlap. This increases significantly the speed of the algorithm. The forces applied during the transformation of the system into a non-overlapping one are expressed as a function of material parameters and geometry.
