Introduction

In 2013, the total number of human *Salmonella* cases remained at a level similar to the two previous years with 1,136 reported cases. The number of *S. Enteritidis* cases increased considerably compared to previous years, primarily due to a large travel-related outbreak of *S. Enteritidis*, where 88 cases were known to have visited Turkey during or just prior to disease onset. The number of cases infected with *S. Typhimurium* or monophasic Typhimurium-like strains and other serotypes decreased and were at the lowest observed for decades.

Ten *Salmonella* outbreaks were reported in 2013 of which seven were domestic; two of these outbreaks were caused by *S. Typhimurium* in pork. 2013 was a year with more travel-related outbreaks than usual; three *Salmonella* outbreaks and two outbreaks with other causative agents taking place at tourist destinations were reported, compared to none in 2012 and two in 2011. The most severe outbreak in 2013 was a large Nordic outbreak of hepatitis A virus with 117 cases, including 72 Danish cases. The source of the outbreak was narrowed down to frozen strawberries most probably originating from Morocco or Egypt.

No human cases were attributed to domestic broiler meat in 2013 according to the *Salmonella* source account. This was the third year in a row. In total, 52% of all human cases was estimated to be travel related; 40% was sporadic cases and 12% was known to be part of travel-related outbreaks. This was similar to previous years. For the cases not related to travel, Danish pork (11%) was estimated to be the most important source and increased compared to 2012 (8%), although this was mainly due to the two outbreaks related to this source, as the proportion of sporadic cases attributed to this source was at a similar level in these two years. The cases attributed to beef decreased again after a considerable increase last year.

The number of human *Campylobacter* cases in 2013 (3,766 cases) remained at a level similar to 2012 (3,728 cases) and thereby continues to be the most commonly reported zoonotic pathogen in Denmark, contributing more than 50% of all cases.

Whole genome sequencing

In recent years, new DNA-sequencing techniques have been developed and made available for easy and fairly cheap sequencing of bacterial genomes. In the near future, this will enable laboratories to implement whole genome sequencing (WGS) as a replacement or complement to existing typing methods. WGS has already proved very useful in the surveillance of human listeriosis, where Statens Serum Institute implemented the method in 2013. WGS has also been applied with success as a tool in the analysis of isolates from two human *Salmonella* outbreaks. During an *S. Bareilly* outbreak in 2013, WGS of human and broiler isolates of this relatively rare serovar made it possible to conclude that the two groups of isolates must have had a close common ancestor, but the infected broiler flock did not seem to be the direct source of the outbreak. Based on these first and promising uses of WGS it is concluded that WGS will be of great value in future cluster detection and outbreak investigation, and initiatives will be taken to make sure that sharing of WGS data between the laboratories at Statens Serum Institute and the National Food Institute also remains plausible in the future.

*Salmonella* in table eggs

The last two decades of intensive *Salmonella* control and eradication programmes in the Danish table egg production have been highly successful, and in the last ten years only few flocks have been found *Salmonella* positive.

In order to evaluate the effect of an abolishment of the warning against the use of raw eggs in dishes eaten without heat treatment, the Danish Veterinary and Food Administration asked The National Food Institute to estimate the relative risk of salmonellosis resulting from increased use of raw eggs by consumers. A model was developed and used for estimating the risks for a number of different scenarios, where different factors such as interval between routine testing, prevalence in countries from which eggs are imported and proportion of Danish laying hen flocks infected with *S. Enteritidis* varied. Based on all

The Annual Report on Zoonoses presents a summary of the trends and sources of zoonotic infections in humans and animals, as well as the occurrence of zoonotic agents in food and feeding stuffs in Denmark in 2013. Greenland and the Faroe Islands are not represented. The report is based on data collected according to the Zoonoses Directive 2003/99/EC, supplemented by data obtained from national surveillance and control programmes as well as data from relevant research projects. Corrections to the data may occur after publication resulting in minor changes in the presentation of historical data in the following years report. The report is also available at www.food.dtu.dk.
the known factors and results, the Danish Veterinary and Food Administration abolished the recommendation to consumers on using pasteurised eggs in dishes that are not heat treated. However as eggs are biological products it is not possible to give a 100% guarantee that all eggs are free from _Salmonella_. The recommendation to use pasteurised eggs, if the dishes are meant for vulnerable consumers like elderly, immunosuppressed or children was maintained.

**Salmonella Dublin in cattle**

In 2002, a national surveillance programme for _Salmonella_ Dublin in cattle was initiated in Denmark. The main purposes were to monitor the national and regional prevalences in the cattle population over time and to provide farmers with a tool to protect their herds against introduction of S. Dublin. All Danish cattle herds are classified into three levels of infection based on repeated antibody measurements in bulk tank milk, individual blood sampling, bacteriological cultivation of herds with clinical outbreaks of salmonellosis and cattle trade patterns. The programme rapidly had an effect on trade behaviour and the trend in the proportion of herds not assumed to be free from S. Dublin decreased. After a period of stagnation, a national eradication plan was initiated in 2007. The third and last step of this plan was set in place in 2013. This step include a regionalisation of Denmark into high prevalence and low prevalence regions, with movement of animals from high to low prevalence regions generally prohibited, and compulsory eradication of S. Dublin in infected herds.

**Salmonella Choleraesuis and Salmonella Typhimurium DT41**

In late 2012 _Salmonella_ Choleraesuis, a serovar linked to the pig reservoir with the potential to cause severe clinical disease in pigs and humans, was observed in a Danish pig herd for the first time since 1999, followed by two additional findings in 2013. However, it has not been possible to identify the primary introduction of this pathogen.

After a very low incidence of _Salmonella_ in the Danish broiler and table egg production in the beginning of 2013, an unusually high number of flocks with _S._ Typhimurium DT41 was observed in the last quarter of 2013. This particular type was isolated from both hatcheries, production flocks, at slaughterhouse and from feed. After additional subtyping of the isolates coupled with epidemiological investigations, the source of the sudden increase of _S._ Typhimurium DT41 in the poultry production remained unclear, although it could be concluded that a combination of spread within the production pyramid and new introductions had played a role. No human cases infected with _S._ Choleraesuis or the relevant subtypes of _S._ Typhimurium DT41 were reported in 2013.

**Risk assessment and predictive microbiology tools available online**

Two user-friendly tools for risk assessment and predictive microbiology developed at the National Food Institute are freely available on the internet; TriMiCri and Food Spoilage and Safety Predictor (FSSP) software.

TriMiCri is a tool, which aims at facilitating the establishment and application of risk based microbiological criteria on _Campylobacter_ in broiler meat. TriMiCri can e.g be used to apply the Danish case-by-case risk assessment approach for the users own situation or to evaluate the expected effect of setting specific microbiological criteria in terms of effect on consumer health risk and the percentage of (potentially costly) non-complying food lots.

The Food Spoilage and Safety Predictor (FSSP) software contains various models to predict the effect of product characteristics and storage conditions on shelf-life and safety of food. The software can among many other things be used to document if _Listeria monocytogenes_ is able or unable to grow in a product.
1. Trends and sources in human salmonellosis

By Leonardo de Knegt (ledkn@food.dtu.dk) and Tine Hald

In 2013, *Salmonella* was the second most common cause of bacterial foodborne infections in Denmark with 1,136 cases reported. During the last three decades, broilers, pigs and laying hens have been ascribed the role of main reservoirs for this pathogen in different time periods, thus demanding different control strategies in the food chain [1]. In order to identify the main food-animal sources of human salmonellosis, Denmark has since 1995 relied on the routine application of a source attribution model. The source attribution model compares the number of human cases caused by different *Salmonella* subtypes with the distribution of the same subtypes isolated from the various food-animal sources.

**New MLVA-based *Salmonella* source account**

Until 2012, the subtyping methods used to characterize human cases and animal samples were serotyping, followed by phage typing of *S.* Enteritidis and *S.* Typhimurium. Antimicrobial resistance profiles of *S.* Typhimurium isolates were also included to further distinguish between similar phage types. Based on an opinion published in 2010 by the European Food Safety Authority [2], strains with just one phase of the H-antigen (e.g. *S*.1,4,[5],12:i:-) are considered “Monophasic *S.* Typhimurium” in the source account.

Phage typing of *Salmonella* has been applied for surveillance, source attribution and outbreak investigations in Denmark since the mid-nineties. It is a phenotypical method that depends very much on the experience of the laboratory doing the typing and on the maintenance of a reference phage collection [3]. Frequently, phage typing has been supplemented with the use of molecular methods, such as pulsed-field gel electrophoresis (PFGE) or multiple locus variable number tandem repeat analysis (MLVA), to improve the discrimination of *Salmonella*.

---

**Figure 1.1. Total incidence of human salmonellosis and estimated human incidence due to domestic broilers, pork, table eggs and imported meat products in Denmark, 1988 to 2013**

Note: In 2013, imported sources may be underestimated, as imported ducks were not included for lack of data, and imported beef corresponds to an estimation based only on *S.* Dublin from previous years (2009-2012).

Source: Danish Zoonosis Centre, National Food Institute
subtyping for detection of outbreaks and identification of outbreak sources [3-6], and efforts are currently being made to establish MLVA as a tool for *Salmonella* surveillance in several countries [5, 7]. Starting with the 2013 data, MLVA substituted phage typing as the subtyping method for isolates of *S. Enteritidis* and *S. Typhimurium* from animal or food samples originating from surveillance or monitoring programs, as well as from clinical human cases in Denmark. Serotyping, as well antimicrobial resistance profiling for *S. Typhimurium*, are still performed.

The MLVA profiles for *Salmonella* are defined by the number of repetitions observed in five independent loci, namely SE9, SE5, SE2, SE1 and SE3 for *S. Enteritidis*, and STTR3, STTR6, STTR10, STTR5 and STTR9 for *S. Typhimurium*. Compared to phenotypical methods, MLVA provides a more detailed profiling of isolates. However, the source attribution model used in Denmark depends on a perfect match between the *Salmonella* subtypes from human cases and animal reservoirs, and therefore a full MLVA profile may be too discriminatory for attribution purposes. Therefore simplified MLVA profiles for *Salmonella* isolates from 2009 and 2010 were tested in different model adaptations. The models with the best fit for each profile were chosen, and the results compared with the results from the phage type-based model from the same years. The selected profile for *S. Typhimurium* is composed by loci STTR3, STTR10 and STTR9, while for *S. Enteritidis* a profile with all five loci was selected.

Since 2008, data from multiple years have been used in the model to improve the robustness and accuracy of the results, but a single year’s results are based on that year’s data only. As MLVA is a newly-introduced method in the Danish surveillance system, data from previous years were not available, and therefore the 2013 model included only one year of data.

Secondly, the change in typing method and differences in profile matching means that some shifts in the attributed shares are to be expected, when compared to results from previous years. Thirdly, the amount of data available for feeding the model changed from 2012 to 2013. In 2013 no data were available from imported beef or imported ducks. The number of cases attributed to imported beef was calculated using the proportion of cases of *S. Dublin* from imported beef in 2009 to 2012 to estimate the 2013 *S. Dublin* cases from this source. This means that the overall contribution of cases from imported food is likely to be underestimated, given the absence of data.

**Salmonella source account 2013 - results**

The incidence of human salmonellosis in 2013 was 20.3 cases per 100,000 inhabitants, including an increase of the incidence of *S. Enteritidis* (6.2), when compared to an incidence of 4.3 reported in 2012. The incidence of *S. Typhimurium*, on the other hand, decreased from 7.3 to 6.0, with a decrease in both typical and monophasic strains (3.7 and 2.3 from 4.0 and 3.4 respectively) (Appendix Table A2).

The overall trend in human salmonellosis cases attributable to the major food-animal sources is presented in Figure 1.1. The most important food source of salmonellosis in Denmark in 2013 was estimated to be domestic pork (Figure 1.2 and Appendix Table A1), to which 11.3% of all *Salmonella* cases were attributed. This represents an increase when compared with the previous year, where 8.0% of the cases were attributed to domestic pork. Ex-

Trends and sources in human salmonellosis

Where do we acquire *Salmonella* infections?

By Luise Müller (lum@ssi.dk)

In 2013, as in the previous years, Statens Serum Institut attempted to interview all registered *Salmonella* cases where no travel information was reported by the general practitioner. The patients were asked about the date of disease onset and whether they had travelled abroad within a seven-day period prior to disease onset. This information was complemented with information from general practitioners' reports. Travel information was obtained from a total of 67.8% of the *Salmonella* cases in 2013. Among the cases with known travel history, 52.1% were infected abroad (Table 1.1).

However, the proportion of travel-related cases varied greatly between the different serotypes hence 79.0% of the *S. Enteritidis* cases, 17.5% of the *S. Typhimurium* cases, 32.5% of the monophasic *S. 1,4,[5],12:i:-* cases and 52% of cases with other serotypes were infected abroad. The distribution pattern of travel-related and domestically acquired *Salmonella* infections (not including outbreak related cases) was comparable to previous years (Figure 1.4). In 2013, Turkey was the country where most of the travel-related cases were infected (31%) and this was mainly due to a large outbreak of *S. Enteritidis* on the south-east coast (see chapter 2). Apart from that most travel-related cases were infected in Thailand (15%), Egypt (8%), and Spain (6%).

Trends and sources in human salmonellosis

From the 78 S. Typhimurium cases with information on antimicrobial resistance, which were attributed to domestic products in 2013, 30.9% were caused by strains susceptible to all tested antimicrobial agents, 66.6% by strains resistant to one to three antimicrobial agents, 1.3% by strains resistant to four or more antimicrobial agents (multi-resistant) and 1.2% by strains resistant to quinolones (Figure 1.3). This is the first time since 2010 that quinolone-resistant strains are observed in human cases attributed to domestic food-animal reservoirs, and reflects the return of multi-resistant strains in domestic pork, where no multi-resistant strains were observed in 2012. Multi-resistant strains were isolated from 44.4% of S. Typhimurium cases with information on antimicrobial resistance which have been attributed to imported products. This is a change from last year, when this profile was not observed. Cases attributed to imported products with resistant Salmonella strains increased from 46.6% to 55.6%, and no fully susceptible strains were observed in 2013 in those sources. From the 38 S. Typhimurium cases acquired abroad for which resistance information was available, 79.3% were caused by resistant types, 17.2% by types susceptible to all tested antimicrobial agents and 3.5% by multi-resistant types.

Molecular serotyping of *Salmonella* isolates

By Jeppe Boel (jboe@food.dtu.dk) and Charlotta Löfström

Serotyping is the standard method for subtyping *Salmonella* and information about serotypes is pivotal for understanding the epidemiology of *Salmonella*. Serotyping is done by slide agglutination using specific antisera that detects differences on cell surface structures: Somatic (O) lipopolysaccharides and flagellar antigens (H). Some *Salmonella* strains, particularly from non-human sources, autoagglutinate (exhibit a rough phenotype) when typed by traditional slide agglutination. This feature is associated with the loss of the outer membrane, which changes the hydrophobicity of the bacteria. Therefore serotyping by agglutination cannot be performed on such isolates and this causes data gaps, when subtyping data is needed, e.g. for *Salmonella* source attribution. To overcome this obstacle, serotypes can instead be determined on DNA level, i.e. by determining the presence of genes encoding the O and H antigens using molecular serotyping.

During 2012 a molecular DNA based serotyping method was implemented at the National Food Institute, Technical University of Denmark, and during 2013 this method was used as a supplement to the traditional serotyping based on agglutination. The DNA based molecular method detects genes mediating the corresponding O and H antigens and thus it is based on the White-Kauffmann-Le Minor scheme. The assay is a multiplex bead-based suspension array based on the Luminex xTAG technology and detects the major O groups and H antigens [1, 2]. It can directly identify the most important serovars of *Salmonella*, but in some cases there is a need to supplement the DNA based data with additional slide agglutination tests. DNA based molecular serotyping has proved to be a valuable tool in the routine typing of *Salmonella*, and further the method enables serotyping of rough isolates.

The possibility to serotype rough isolates was utilized in a study of rough *Salmonella* isolates from pig carcasses obtained in the national surveillance program for fresh meat. A total of 211 rough strains isolated during the period 2005-2012 were analyzed using molecular serotyping. The typing enabled serovar identification of 168 of the strains (80%). The identified serotypes were Typhimurium (n=92; 44% of the 211 strains), Derby (n=40; 19%), 4,[5],12:i:- (n=22; 10%), Infantis (n=8; 4%) and others (n=6; 3%). Serotyping results for strains isolated during the same years from pig carcasses, where traditional serotyping was possible (smooth strains) (n=1,233) showed a similar serovar pattern, where Typhimurium (n=547; 44%), Derby (n=399; 32%) and 4,[5],12:i:- (n=72; 6%) also were the most commonly identified serotypes. Studies are in progress to serotype the remaining 43 rough strains that could not be typed in the first approach, using other DNA based techniques to further assess the difference in results between molecular and traditional serotyping. In conclusion, our preliminary data suggests that molecular serotyping of rough *Salmonella* strains mirror the serotypes obtained using traditional serotyping for smooth strains.

2. Food- and waterborne outbreaks

By the Central outbreak management group

Food- and waterborne outbreaks in Denmark are reported in the Food- and waterborne Outbreak Database (FUD). Outbreaks that occurred in 2013 are presented in Appendix Table A4. Figure 2.1 shows the relative distribution of these outbreaks by the different causative agents. Household outbreaks and clusters that could not be verified as common source outbreaks are not included. The outbreak investigation procedures in Denmark are described in further detail in Chapter 10.

In total, 74 foodborne outbreaks were reported to FUD in 2013 (Appendix Table A4) which is a decrease from 2012, where 82 food- and waterborne outbreaks were reported. There were no notifications of waterborne outbreaks in 2013. The outbreaks were mainly regional outbreaks (93.2%) and only five outbreaks were national outbreaks with patients distributed over several regions. The largest of these outbreaks was caused by hepatitis A virus. Compared to previous years an increase in travel related outbreaks was observed (five reported in 2013, none in 2012 and two outbreaks in 2011).

In total, the number of persons affected by foodborne outbreaks was 2,066 persons with a median of 12 persons per outbreak (range 2 – 425). The largest outbreak involving 425 persons was an outbreak caused by Clostridium perfringens. All affected persons had dined at the same event, and the outbreak investigation conducted by the Food Control Office in Northern Jutland, pointed out patty shells with sauce containing hen meat and asparagus as the source of infection (FUD1325). As in previous years norovirus (NoV) was the most frequent cause of foodborne outbreaks (28 outbreaks) and in total, 655 persons were affected by NoV outbreaks. The transmissions routes of NoV causing foodborne outbreaks are multiple. In Table 2.1 a breakdown of the number of outbreaks and the persons affected per route of infection for 2013 is shown. From the data it is evident that the most common ways of infection was contamination from either an ill dining guest attending a buffet and thereby contaminating the buffet (cutlery or food items) or a member of the kitchen staff contaminating the food. Less often the infection originated from contaminated ready-to-eat products like oysters and frozen berries.

In 2013 Clostridium perfringens was more frequently associated with foodborne outbreaks than in previous years. In total, 16 outbreaks of C. perfringens affecting a

1. The Danish Veterinary and Food Administration (DVFA) is one authority but operates from more locations throughout the country. To be able to distinguish the locations the terms DVFA is used synonymous with the location in Glostrup and Food Control Office (FCO) synonymous with the location in question.
total of 753 persons were reported in 2013, compared to eight and seven outbreaks caused by this agent in 2012 and 2011, respectively.

When dividing the outbreaks into reported settings, "Restaurants, cafés and bars" was the most frequent setting (45.9%) with 34 reported outbreaks affecting 984 persons (mean: 29 persons per outbreak). Outbreaks taking place in workplace canteens (10 outbreaks) also affected a high number of persons (327 persons) and on average had slightly more persons per outbreak than "Restaurant, café and bar outbreaks" (mean: 33 persons per outbreak). Composite meals (25) and buffet meals (25) were the most frequently reported source of outbreaks in 2013 and most often these outbreaks were associated with NoV and *C. perfringens* (Appendix Table A4).

**Outbreaks with Salmonella**

In 2013, ten *Salmonella* outbreaks were reported in FUD, where three of these outbreaks were related to persons travelling abroad. Five domestically acquired outbreaks of *S. Typhimurium*, one outbreak of *S. Enteritidis* and one outbreak of *S. Mikawasima* were reported. Two of the national outbreaks of *S. Typhimurium* were suspected to have been caused by Danish produced pork. The first one was an outbreak of *S. Typhimurium* MLV A type 0007 with a resistance pattern rarely seen for this MLV A type; Ampicillin, Streptomycin and Sulfamethoxazole (ASSu) (FUD1245) and was a continuation of an outbreak with 12 patients already reported in 2012. Further investigation was initiated and the patients were interviewed. In total, 22 patients were identified with date of onset of illness from November 2012 to April 2013. The patients were 11 females and 11 males aged 1-82 years (median 62 years). The majority of patients lived in the eastern part of Denmark, primarily on the island of Falster. This outbreak was severe as several patients were hospitalised and two patients – aged 71 and 79 years - died within three weeks after the infection. However, it was not possible to explain all patients from this outbreak MLV A-typing of selected *S. Typhimurium* ASSu isolates from pig slaughterhouses obtained in the same period.

The second outbreak was caused by *S. Typhimurium* U312 MLV A type 0550 fully sensitive to antibiotics (FUD1254). A total of 43 patients were reported from January to May 2013. The patients were 24 females and 19 males aged 0-94 years (median age 51 years). The patients were from all over Denmark. Interviews pointed at pork meat as the possible source. Fully sensitive *S. Typhimurium* isolates from the *Salmonella* surveillance and control of food and animals in Denmark were selected for MLVA typing. Thirty-two isolates mainly from October 2012 to January 2013 and mainly from pig slaughterhouses or pork samples were typed by MLVA. The outbreak MLVA type was detected in two isolates from pork isolated during January 2013. The isolates were from a medium-sized pig slaughterhouse and from a cutting plant receiving meat among others from the above-mentioned slaughterhouse, however it was not possible to explain all patients from this source and no final conclusions could be made of the origin of the meat, although a strong indication towards the source being a pork product was obtained.

**Nordic hepatitis A outbreak**

In February 2013, Statens Serum Institut saw an increase in the number of domestically acquired hepatitis A cases (FUD1259) [1-4]. The cases were geographically distributed all over the country and did not belong to any of the known risk groups (drug users, men having sex with men, homeless people and travellers to endemic countries). Subtyping of the hepatitis A virus (HAV) showed that the majority of cases were genotype 1B with two closely related sequences indicating a common foodborne source. After extensive

interviews with the initial cases, a case-control study was performed pointing out frozen berries and strawberries in particular – used without heat treatment in e.g. desserts and smoothies - as the most likely source of the outbreak. The Danish Veterinary and Food Administration then issued recommendations to heat treat all frozen berries before consumption. An international inquiry revealed that cases had also been reported in Norway, Sweden and Finland. Case-control studies were performed in these countries and a joint analysis of the results pointed out frozen strawberries to be the source of infection. In total 117 cases were identified with date of onset from October to November 2013 (Figure 2.2). The majority of cases was from Denmark where 72 cases were registered from October 2012 to August 2013. Of these 43 (60%) were females and 29 (40%) were males. Cases were 2-81 years old with the median age of 22 years. Seven cases were considered to be secondary cases. Norway reported 7 cases, Sweden 22 cases and Finland 16 cases.

An extensive food source trace-back investigation involving all four countries was performed. The investigation was performed using purchase data collected from patients (receipts) and where possible, information on purchase of berries was obtained by using the supermarkets data on exact purchase by patient credit cards. Information from the packages of berries and fruit sampled for virological testing was also included in the investigation. This information pointed at frozen strawberries provided by a specific packaging establishment in Belgium. Presented with this information, the supermarket chain retailing the product in

Denmark made a voluntary recall of this product. Further trace-back investigation performed by the Danish Veterinary and Food Administration in cooperation with the supermarket chain and the Belgian establishment narrowed the possible vehicles down to strawberries most probably originating from either Morocco or Egypt, and from the harvest year 2012. In all, 57 samples of frozen berries and frozen mango fruit were tested (20 from Denmark, 14 from Finland, 11 from Sweden, 12 from Norway). The samples were collected in the patients’ homes and from retail shops identified during the investigation. The National Food Institute, Technical University of Denmark investigated the Danish and Finnish samples. Unfortunately, it was not possible to detect hepatitis A virus in any of the tested samples. There might be several explanations for that, including uneven distribution of virus in berries, limitations in method sensitivity, or simply because the bags tested did not contain the virus. In conclusion, this outbreak was a very large and long-lasting challenge involving both interdisciplinary collaboration between public health institutes, laboratories and food authorities, and also a good example of international collaboration and collaboration with the establishments involved in the trade of frozen berries.

Outbreaks at tourist destinations

In 2013, several outbreaks at tourist destinations involving Danish travellers were reported. In the period from June to October 2013 an increased number of S. Enteritidis cases with six specific subtypes were seen among Danish travellers (FUD1290) [4]. In total, 121 cases were registered and 88 of these were known to have visited Turkey during onset or just prior to disease onset. In comparison, during the previous years’ summer peaks (June to September) 29-37 travel-related S. Enteritidis cases from Turkey were reported annually in 2010-12. Interviews with the cases showed that they had stayed in different hotels and different towns – primarily at the south-east coast of Turkey, so there was no common place of exposure. The interviews showed that cases mainly had booked all-inclusive stays (73%). The interviews also showed that half of the cases had eaten eggs during their stay and since consumption of eggs is considered to be the main risk factor for S. Enteritidis infection, this was the main hypothesis of the source – however, it was not possible to confirm this.

In the end of July 2013 an outbreak of gastroenteritis among children from four Nordic countries staying at the same hotel in Turkey was reported (FUD 1302) [5]. A total of 61 laboratory confirmed cases were reported from Norway (23), Sweden (27), Finland (3) and Denmark (8). The laboratory results showed a mix of S. Enteritidis, Shigella sonnei and Verotoxin producing Escherichia coli (VTEC). A cohort study in Norway pointed out slush-ice as the most likely source of infection.

An international outbreak was seen from November 2012 – April 2013 with hepatitis A virus (HAV) in travellers returning from Egypt (FUD 1277) [6]. In total, 15 confirmed cases of HAV infections with genotype 1B and identical RNA sequence of which 9 were identified in Denmark, and 89 probable cases, were reported in 14 other EU/EFTA countries. All 104 cases had been travelling to Egypt. An international case-control study was conducted. It was not possible to identify the source of the outbreak; however, the results indicated that consumption of strawberries or mango fruit could have been involved [7].

In October 2013, a Danish travel agency informed about an outbreak from a specific hotel in Tunisia (FUD 1307). Further investigation identified five cases in the Danish surveillance system with Shigella sonnei infection and travel to Tunisia. In comparison 0 -1 case have been reported each year from 2009-2012. Interviews with four of the five cases showed that they had stayed at the same hotel during the first two weeks in August 2013. Three patients had not been eating outside the hotel. An international inquiry did not reveal cases from other countries. Outbreaks implicating Danish tourists in other countries are difficult to investigate and it was not possible to confirm the sources of any of the above-mentioned outbreaks. However, for several of the outbreaks the Danish tourists have stayed at resorts and have only eaten at the hotels and it is likely that these places are not perceived as risk areas. Efforts should be made to make tourists aware of the risks and preventive measures such as taking general hygiene precautions even when staying at closed resorts with all inclusive, and getting vaccinated against HAV when travelling to endemic areas.

3. Whole genome sequencing

By Mia Torpdahl (mtd@ssi.dk), Charlotte Løfstrøm and Eva Møller Nielsen

In recent years, new DNA-sequencing techniques have been developed and made available for easy and fairly cheap sequencing of bacterial genomes. These post-’Sanger’ sequencing techniques are commonly referred to as ‘next-generation-sequencing’ (NGS). NGS includes sequencing technologies that have high sequence capacity, but produce short sequences (e.g. as developed by Illumina and IonTorrent), which is compensated for by high sequence coverage (Figure 3.1). This technological development has dramatically reduced the cost of determining the complete, or nearly complete, genetic information for bacterial isolates. The technology and price will in the near future allow reference laboratories to implement whole genome sequencing (WGS) for typing of bacterial isolates as a replacement or complement to the conventional phenotypic and molecular typing methods.

The use of WGS for epidemiological purposes, such as routine surveillance and outbreak investigations, rely on the analysis of the large amount of data produced. Presently, there are two main approaches for analysing data, the mapping of sequence reads to a reference and “de novo” assembly (without a reference). These approaches can be used independently or in combination. The sequences from different bacterial isolates can be compared to each other directly e.g. by identifying single-nucleotide polymorphisms (SNPs) compared to a reference or gene-by-gene comparisons across assembled genomes. Conventional typing information can also be extracted. Currently, the analytical approaches are still under development and no international standards have been decided on for comparing bacterial isolates based on WGS data.

In the last two years, the use of WGS of foodborne bacteria has been under development at Statens Serum Institut and the National Food Institute, Technical University of Denmark, for epidemiological purposes. At both institutes, WGS has been used for several outbreak investigations in 2012-2013 and WGS was tested for the routine surveillance of VTEC infections for a 3-months period in 2012 [1]. Furthermore, Statens Serum Institut implemented WGS for the continuous surveillance of listeriosis in 2013. The analytical approaches used for the routine surveillance might be markedly different from the approach used in outbreak situations where a limited number of closely related isolates are compared, e.g. by SNP-based analysis.

Surveillance of listeriosis

The surveillance of listeriosis cases in Denmark is based on the ‘real-time’ typing of isolates from all human infections. The regional clinical laboratories submit the isolates to Statens Serum Institut where typing is performed and used for early detection of outbreaks and the surveillance of trends over time. For the past ten years, isolates have been typed by pulsed-field gel electrophoresis (PFGE) (Annual report on Zoonoses 2011). Although PFGE with two restriction enzymes is internationally standardized and gives a good discrimination for typing of Listeria, PFGE is relatively labour-intensive to perform on a few isolates at a time and PFGE-profiles can generally be difficult to interpret and compare. As replacement of PFGE and other characterisation methods used for Listeria isolates, Statens Serum Institut implemented WGS for surveillance of listeriosis in 2013. The incoming isolates are sequenced on a weekly basis and the aim of the developed pipeline and the analytical approach is to obtain a clear indication of any related isolates and thereby potential outbreaks by an easy and fast analysis. The new isolates should be compared to older isolates in the database without re-analysis of these. Therefore, the analysis is based on extracting the genes from the multiple-locus sequence typing (MLST) method, which has an international standard nomenclature [2]. Only in the situations where isolates with the same MLST type are identified within a few months, a SNP-based analysis is performed to directly compare the relevant isolates.

This algorithm for analysis was developed and validated based on the knowledge obtained from analysing representative isolates from the previous ten years’ surveillance, including isolates with known epidemiological links.

In 2013, 50 cases of listeriosis were registered. In concordance with the PFGE-based surveillance, WGS showed that the majority of isolates were from sporadic cases. However, five clusters of two to four isolates each were identified. Within these clusters, isolates had the same MLST profile and had less than 10 SNP differences. One cluster seemed to be linked to a specific hospital, but otherwise it was not possible to find a common source of infection or any other link between the patients. Epidemiological investigations of Listeria cases are often quite difficult due to the long incubation period, the high mortality rate and the fact that Listeria cases are often very old and suffer from underlying diseases.

WGS is a cost-efficient method for typing if used as the only laboratory method, i.e. if the hitherto used methods (serotyping and PFGE) are discontinued. As always when shifting laboratory methods, this can give problems with comparability between laboratories and countries in a transient period. Statens Serum Institut has implemented WGS
for typing of *Listeria* isolates from human cases of infection before national or international systems for exchange of WGS-typing data is available. However, the principle of extracting the seven MLST loci with an established nomenclature from the NGS raw data (possible extended with more loci in the future) gives optimal conditions for easy exchange of typing results, as the results are independent of the bioinformatics tools used in each laboratory, e.g. for assembly and SNP-calling.

However, PFGE is the standard method for *Listeria* typing in Europe – for typing of human isolates as well as food isolates – a PFGE profile will still be produced for outbreak isolates for national and international comparison, including upload to ECDC’s Molecular Surveillance System.

**WGS for Salmonella cluster investigations**

The national surveillance of human *Salmonella* cases is based on the ‘real-time’ typing of isolates from human infections by serotyping of all isolates, multiple-locus variable number of tandem repeats analysis (MLVA) of the two most frequent serotypes (Enteritidis and Typhimurium, including the monophasic variant) and PFGE of other serotypes. Results are used for cluster analysis, outbreak investigations, comparison with food and animal isolates as well as making international inquiries. There are some interpretative implications that have to be considered when using PFGE in outbreak investigations, e.g. the significance of minor band differences when defining clusters within different *Salmonella* serotypes. In 2013, Statens Serum Institut investigated the use of WGS for cluster detection and analysis of *Salmonella*. The incoming isolates were screened for clusters based on serotype and when potential outbreaks emerged, isolates were selected for sequencing. Two clusters appearing in the autumn were investigated using WGS, one being the rare serotype Mikawasima and the other the more prevalent serotype Agona (Figure 3.2). Mikawasima isolates from patients in 2012 (6 isolates) and 2013 (12 isolates) were analysed by WGS and PFGE. The 11 isolates from October and November 2013 clustered together by both methods. Analysis of WGS data showed that the isolates in this cluster had no SNP differences, whereas all other isolates clustered into several groups more than 70 SNPs apart (Figure 3.3). The cluster isolates displayed the same unique PFGE profile although the profiles found in Mikawasima isolates generally showed high similarity (Figure 3.3). The data indicate that the increase in Mikawasima seen in October and November 2013 was an outbreak. It also showed another cluster from 2012 consisting of 3 cases. The SNP tree and the PFGE data showed a high degree of concordance, although the sequence data had a higher resolution in comparison to
The 16 *S. Agona* isolates received from February to November 2013 were analysed by PFGE and WGS. Both PFGE and WGS data identified the same 8 isolates received during August to November as being part of an outbreak. However, WGS data had a higher resolution and separated isolates with indistinguishable PFGE profile in correlation with age group and date of isolations, indicating a unique epidemiological relationship among these isolates.

WGS has also been evaluated as a tool to compare *Salmonella* isolated from humans and foods in outbreak investigations and to investigate the plausibility of sharing data and results between the laboratories at Statens Serum Institut and the National Food Institute, Technical University of Denmark. One example is an outbreak in 2012 where seven patients were infected with *S. Bareilly* with an identical PFGE profile. Patient interviews traced the source to unidentified food served at a specific restaurant [3]. At the same time four broiler flocks were tested positive for *S. Bareilly*. PFGE profiles from the veterinary and human isolates were found to differ by two bands. WGS results showed that the broiler and human isolates belonged to the same MLST type and that they were divided into two closely related groups based on SNPs. It was concluded that there was a close common ancestor of the two isolate groups, but that the broiler flock did not seem to have been the direct source of the human outbreak [4]. Although the same conclusion was drawn based on PFGE and WGS data, a more precise determination of the relationship between isolates was obtained using WGS thereby contributing to the conclusions of the outbreak investigation.

From these first and very promising uses of WGS analysis for cluster investigations on human *Salmonella* infections and outbreak investigations of food and human isolates, we therefore conclude that WGS is a highly sensitive method that will contribute tremendously in cluster detection and outbreak investigations. Over the next few years it is the goal at Statens Serum Institut to replace the current flow of different subtyping schemes in *Salmonella* with one method and therefore implement WGS for *Salmonella* for the national human surveillance.

At the National Food Institute, WGS is planned to be implemented within a few years’ time and used as a complement or to replace existing typing methods. In line with this, a PhD project was initiated in 2013 aiming at evaluating different approaches suitable for application of WGS in a routine laboratory setting. In this project cases related to outbreak investigations will first be investigated and thereafter, using the experiences gained, strategies for applying WGS for surveillance of e.g. *Salmonella* will be investigated. During this process it will be important to harmonize the protocols used in order to assure that data can easily be exchanged between SSI and DTU, e.g. in joint outbreak investigations.
WGS for the future surveillance of foodborne infections/zoonoses in DK

The vision for implementing WGS in reference laboratories is that analysis of WGS-data can replace the multitude of different methodologies presently used for characterisation of bacterial isolates, e.g. serotyping, PCR/Sanger sequencing for determining virulence factors and antimicrobial resistance genes, antimicrobial resistance profiling, and molecular typing methods for high discriminatory typing. If the relevant information can be extracted from WGS data, it will be cost-effective to replace the conventional methods by routine WGS in the surveillance of foodborne infections. Statens Serum Institut and the National Food Institute, Technical University of Denmark are working on further developing and implementing WGS for characterisation of foodborne pathogens such as verotoxin-producing *E. coli*, *Salmonella*, *Listeria* and *Campylobacter*. The great benefits of WGS will be achieved when tools are developed for extracting key conventional typing information, primarily the serotype of *Salmonella* and *E. coli*. Conventional serotyping has formed the primary categorization of these organisms for decades and it can be anticipated that serotype information will still be important for a period of several years to come. This will allow the discontinuation of conventional serotyping in laboratories performing WGS as they will still be able to compare to laboratories only performing the conventional serotyping. In contrast, it is less likely that backwards comparability is feasible and important for typing methods like PFGE. To enable sharing of data between different laboratories, it is important to assure that harmonized protocols are applied.

4. Relative human risk of *Salmonella* Enteritidis in table eggs in Denmark

By Helle Korsgaard (hkor@food.dtu.dk), Tina Struve, Tine Hald and Håkan Vigre

Since 1980, the use of raw (unpasteurised) eggs in dishes that are not thoroughly heat treated has not been permitted in restaurants, canteens and other public food handling businesses in Denmark. Since the late-1990s consumers have also been advised to avoid using raw eggs in dishes that are not heat treated, such as certain desserts and cakes.

In Denmark, laying hen flocks are tested intensively for *Salmonella* and when a flock is found positive, eggs from this flock are subjected to heat treatment. However, eggs from infected flocks can reach the retail market as table eggs during the period between the time of infection and when the routine testing reveals the *Salmonella* infection.

The last two decades of intensive *Salmonella* control and eradication programs in the Danish table egg production have been highly successful, and in the last ten years only few flocks have been found *Salmonella* positive (Appendix Table A6).

In order to evaluate the effect of the possible abolishment of the warning against the use of raw eggs in dishes eaten without heat treatment, the Danish Veterinary and Food Administration asked The National Food Institute, Technical University of Denmark, to estimate the relative human risk of salmonellosis resulting from increased use of raw eggs by consumers. The relative human risk was to be estimated for the current testing intensity (every 9th week) and for a more intensive program with testing every 2nd week.

In Denmark, most of the table eggs available at retail are domestically produced (97% in 2008-2010). The rest is primarily imported from Sweden and Finland where the occurrence of *Salmonella* in poultry is very low. A second question from the Danish Veterinary and Food Administration was to estimate the changes in relative human risk, if imported eggs available for consumption were to originate from other EU Member states with higher levels of *Salmonella* among laying hen flocks.

**Risk modelling**

To answer the questions, a probabilistic simulation model was set up to describe the infection dynamics of *Salmonella* during table egg production. In the model, the Danish consumer’s risk of purchasing contaminated table eggs depends not only on the risk of introduction of *Salmonella* into a laying hen flock, but also on how fast the infection spreads within the flock, the total number of eggs produced and the frequency and sensitivity of the routine testing.

The Danish *Salmonella* source account (chapter 1) shows that domestically acquired human infections attributed to table eggs are primarily caused by *S.* Enteritidis, even though other serotypes such as *S.* Typhimurium are also detected in Danish flocks of laying hens. Therefore, it was decided that the model only should include introduction and spread of *S.* Enteritidis.

**Proportion of eggs produced by infected birds**

On average 0.8% of the laying hen flocks tested in 2008-2010 were found positive for *S.* Enteritidis by the Danish control program (testing every 9th week), and the model predicts that 0.03% of the Danish table eggs reaching retail were produced by infected birds. In comparison, the model predicts that sampling every 15th week would have increased the proportion of Danish eggs produced by infected birds reaching the market by a factor of almost two, whereas a more intensive routine testing (every 2nd week) would have reduced the proportion to a fifth. Please note that the model predict number of eggs produced by infected birds, not the number of contaminated eggs.

In 2013, *S.* Enteritidis was detected in one of 373 laying hen flocks (0.3%). In October 2013, the routine testing of Danish laying hen flocks changed from every 9th week to every 2nd week. Assuming the same risk of infection per flock every day during 2013, the model estimates that during the first nine months (testing every 9th week) an
estimated 0.014% of the Danish eggs were produced by infected birds compared to an estimated 0.003% during the last three months (testing every 2nd week).

**Estimating the relative human risk**

To simplify the model, we assume there is a direct correlation between the number of human *S.* Enteritidis cases caused by consuming raw table eggs in non-heat treated dishes and the proportion of table eggs on the retail market produced by infected birds, given that:

- The proportion of contaminated eggs produced by the infected birds is the same in all scenarios.
- One table egg equals one portion consumed by one person.
- Infection of one or more persons due to cross contamination is not considered.

The relative human risk is calculated as:

\[
RR_{\text{scenario}} = \frac{\text{Risk}_{\text{scenario}}}{\text{Risk}_{\text{baseline}}}
\]

where the 'Risk' is the estimated mean proportion of table eggs available at retail produced by infected birds. By assuming the same proportion of *S.* Enteritidis contaminated table eggs in all scenarios, the estimated relative human risks are independent of the actual proportion of contaminated table eggs produced by the infected birds as well as the actual numbers of human cases caused by *S.* Enteritidis contaminated eggs.

It is unknown how frequently raw eggs are used in non-heat treated dishes in Denmark, both with and without the authorities warning against such use. Therefore, the relative human risk for Danish consumers is estimated assuming 1%, 2% and 5% of the table eggs is consumed without heat treatment.

![Figure 4.1. Relative human risk of *S.* Enteritidis infection for selected scenarios, assuming 1%, 2% or 5% of the table eggs are consumed in non-heat treated dishes](image)

---

*a) Relative human risk for scenario = Risk / Risk_{baseline}, where the risk is the 'mean proportion of table eggs available at retail produced by infected birds,' when 97% of the table eggs originate from Danish laying hen flocks and 3% is imported from other EU Member States (MS)

b) Scenarios where the model varies: the proportion of Danish laying hen flocks infected with *S.* Enteritidis as observed in 2008-2010 (0.7%) and in 2013 (0.3%), the proportion of *S.* Enteritidis infected laying hen flocks in other EU Member States (lower = 0.07%, medium = 1.4% or higher = 2.8% infected flocks), and interval of routine testing of every 2, 9 or 15 weeks.

Source: National Food Institute*
A baseline scenario, set to the value of 1, is estimated assuming:

- 1% of the table eggs are consumed in non-heat treated dishes.
- 97% of the eggs originate from Danish laying hen flocks tested every 9th week during 2008-2010.
- The remaining 3% originate from EU Member States with low levels of S. Enteritidis among laying hen flocks (0.07% positive flocks) tested every 15th week.

**Results**

Figure 4.1 presents the estimated relative human risks for the baseline scenario (set to 1) and the alternative scenarios where the imported table eggs originate from flocks in EU Member States with higher levels of *Salmonella* among the laying hen flocks (1.4% and 2.8% positive flocks). Even though only 3% of the table eggs are assumed to be imported, the relative human risk increases by a factor of 1.1, if the imported eggs originate in EU Member States where *S. Enteritidis* in layer flocks is detected twice as often as the average in Denmark during 2008-2010. If the consumption of raw eggs in non-heat treated dishes also doubles, the relative risk increases by a factor of 2.4.

The proportion of *S. Enteritidis* infected laying hen flocks in Denmark was lower in 2013 (0.3%) compared to 2008-2010 (0.7%), and flocks were tested every 5th week until October 2013 and every 2nd week thereafter. Compared with the baseline situation in 2008-2010, the relative human risk was reduced to 0.4 during the first months in 2013 and to 0.1 during the last months of 2013, assuming 3% of the table eggs available at retail were import from EU Member states with low *S. Enteritidis* occurrence (Figure 4.1.).

When the proportion of eggs produced by *S. Enteritidis* infected birds in Denmark is as low as estimated for the last months of 2013, the contribution of *S. Enteritidis* from imported eggs becomes increasingly important. If 3% of the eggs were imported from an EU Member State with higher occurrence of *S. Enteritidis* (2.8% infected flocks), the relative human risk would more than double (Figure 4.1).

**Conclusion**

In response to the questions raised by the Danish Veterinary and Food Administration, it must be concluded that as long as there are *Salmonella* positive table egg laying hen flocks in Denmark and in the countries from where we import table eggs for direct consumption, there is a risk of salmonellosis when consuming raw eggs in dishes that are not heat-treated. Therefore it must be expected that not warning consumers against the use of raw eggs in non-heat treated dishes may lead to an increased consumption of raw eggs and therefore an increased human risk.

Contaminated eggs will be produced in the period between infection of the flock and until detection of the contaminated flock. Increasing the frequency of routine testing of the Danish laying hen flocks in 2013 from every 9th to every 2nd week decreased the relative human risk by approximately a factor 5.

In order to be able to evaluate effects of changes in consumers’ use of raw table eggs as well as changes in import, the Danish Veterinary and Food Administration was provided with a an Excel tool, giving outputs on the form similar to Figure 4.1. The proportion of eggs imported from different EU Member States can be entered, and then the tool will calculate the weighted mean proportion of eggs produced by infected birds available for the Danish consumers as well as the relative human risk.
In 1997, the number of people suffering from salmonellosis due to the consumption of table eggs was an estimated 3,000, the highest number ever in Denmark. As a consequence the Danish Veterinary and Food Administration introduced a recommendation to consumers about using pasteurised egg products in dishes consumed without prior heat treatment. A requirement for food businesses to heat treat dishes containing raw eggs, alternatively to use pasteurised egg products was already in place in the legislation. The following years Denmark made a huge and successful effort to reduce the occurrence of Salmonella in the table egg production. As a result of the low prevalence of Salmonella achieved, in 2007 Denmark applied to the EU for special guarantees for Salmonella in table eggs [1], a position attained by Sweden and Finland at the time of their accession into the EU in 1995. In July 2012, special guarantees for Salmonella in table eggs were granted to Denmark [2]. This was an acceptance of Danish eggs being as safe as eggs produced in Sweden and Finland. The Danish Veterinary and Food Administration therefore found it necessary to reconsider the current legal requirements for heat treatment of eggs in food businesses and the recommendations to consumers. In order to make the right decision the Danish Veterinary and Food Administration asked the National Food Institute, Technical University of Denmark, to provide advice on the consequences in relation to human health, if the legal requirement and consumer recommendation were repealed.

In October 2013, the Danish Veterinary and Food Administration abolished the recommendation to consumers on using pasteurised eggs in dishes that are not heat treated. As eggs are biological products it is not possible to give a 100% guarantee that all eggs are free from Salmonella. In order to be on the safe side, the Danish Veterinary and Food Administration still recommend the use of pasteurised eggs, if the dishes are meant for vulnerable consumers like the elderly, the immunosuppressed or children.

The requirement for food businesses to heat treat dishes containing raw eggs, alternatively to use pasteurised eggs was maintained. The rationale was that the use of imported eggs is common in the catering sector and these eggs do not necessarily have the same level of safety as eggs produced in Denmark. Also, if a restaurant or a cafeteria serves dishes with raw eggs, the consumer is not necessarily aware of this choice. Consequently the consumer cannot himself make the choice of whether to eat dishes containing raw eggs or not. Finally, hospitals and homes for elderly serve meals for vulnerable groups where the use of a contaminated egg could have fatal consequences. The Danish Veterinary and Food Administration will follow the situation closely, including the number of human cases of salmonellosis from table eggs, and after a period the legal requirement for heat treatment of raw eggs in food businesses will be reconsidered.

5. *Salmonella* Dublin in cattle

By Erik Rattenborg (era@vfl.dk) and Gudrun Sandø

*Salmonella enterica* subspecies *enterica* serovar Dublin (S. Dublin) is a foodborne zoonotic bacteria that can cause severe invasive manifestations in humans [1] and in cattle. S. Dublin is to a high degree host-adapted to cattle, and it can cause both welfare and economic losses in infected herds.

In 2002, a national surveillance programme for S. Dublin was initiated in Denmark. The main purposes were to monitor the national and regional prevalences in the cattle population over time and to provide farmers with a tool to protect their herds against introduction of S. Dublin. Subsequently all Danish cattle herds are classified into one of three levels of infection based on repeated antibody measurements in bulk tank milk, individual blood sampling, bacteriological cultivation of herds with clinical outbreaks of salmonellosis and cattle trade patterns (Table 5.1).

The programme is administered by the Knowledge Centre for Agriculture, Cattle and controlled by the Danish Veterinary and Food Administration.

The programme rapidly had an effect on trade behaviour among cattle farmers. Within the first six months after initiation of the programme, the trading pattern stabilized, i.e. animals purchased into Level 1 herds decreased from random to only 2-3% of animals purchased from Level 2 herds. This was followed by an economical effect, i.e. the market price of live animals from a herd in Level 1 became considerably higher than animals from Level 2.

### Development in infection levels

Since the beginning of the programme, the trend in the proportion of Level 2 herds has been decreasing. Initially the main driver probably was the change in trading behaviour mentioned above [2]. The decreasing trend has not been equal in different types of production (Figure 5.1 and 5.2) and different geographical areas.

In Figure 5.1 the development of the proportion of Level 2 herds is shown for dairy herds and non-dairy herds (all other production types). In Figure 5.2 the trends of the non-dairy herds are specified according to production type.

The motivation for control of the infection within the herds has differed depending on the production type and geographical area. For dairy herds the motivation has been high from the beginning because of the difference in market value of live animals. Among slaughter calf producers the motivation initially was lower because they buy the calves from several dairy herds and continuously received infected calves (Figure 5.2). As these producers do not sell live animals, no economic consequence was imposed on them. Later, however, many of them discovered the positive influence of *Salmonella* control on calf health and these now exclusively buy calves from Level 1 dairy herds.

The difference in prevalence by geographical region is pronounced (Figure 5.3). Regions with low prevalence also reflect areas with few herds (e.g. Zealand). Furthermore the decreasing trend has been proportionally more

pronounced in regions with an initial low prevalence. This is suggested to be attributed to neighbour effects among other reasons [2].

**Further national initiatives**

The decrease in the proportion of dairy herds in Level 2 declined in 2005 and again in 2010. In 2005, the initial effect of the programme had ‘burned off’. Therefore new initiatives were developed and agreed upon between the authorities and the industry.

In 2007 a voluntary eradication campaign was decided by the industry with the aim of eradicating *Salmonella* Dublin from the Danish cattle population. Subsequently in 2008 a national control plan was prepared in a collaboration between the Knowledge Centre for Agriculture, Cattle, Department of Large Animal Sciences at the University of Copenhagen, The National Food Institute at Technical University of Denmark and the Danish Veterinary and Food Administration. The control plan sets means and targets for the reduction in different production types and at carcass level. The overall aim was to eradicate *Salmonella* Dublin from the cattle production by 2014.

The control plan has involved three steps (see text box). In 2010 restrictions were imposed upon Level 2 herds with high ELISA values as live trade was prohibited. New initiatives were outlined in 2012 when also the target of eradication by 2014 was postponed to 2016 because of insufficient progress. The revision came into force July 2013 and includes regionalization of Denmark into high prevalence and low prevalence regions (Figure 5.3). Movement of animals from high to low prevalence regions is generally prohibited, and positive herds in the low prevalence region are placed under official restrictions.

Furthermore all positive herds are obliged to outline an action plan, including herd specific control measures, in collaboration with a veterinarian. The effect of the control measures must be documented and official restrictions are imposed on the herds if there is no progress. The provisions are laid down in order no. 954 of 13th of July 2013 on *Salmonella* in cattle a.o. species.

**References**

### The S. Dublin eradication programme

The eradication has been organized in three phases. The aim of the national strategy is to eradicate *S. Dublin* by 2016. By eradication is meant that the prevalence has to be close to 0% and appearing cases have to be controlled in order not to spread.

- **Phase 1:** Voluntary intervention in infected cattle herds from 2007 to end of 2009. All Level 2 and 3 herds were offered to be part of a network group that meets several times together with a consultant or veterinarian acting as facilitator to inspire each other to keep up the intervention work.

- **Phase 2:** Level 2 herds with high ELISA values were placed under restrictions and live trade was prohibited.

- **Phase 3:** In 2013 regionalisation of the country in low and high prevalent regions was implemented. The partition in low and high prevalent regions by legislation is shown in Fig. 5.3. Furthermore herd specific eradication programmes in all Level 2 and 3 herds is required.
Figure 5.3. Map of Denmark showing high and low prevalent regions and area prevalences

6. Outbreak of *Salmonella* Choleraesuis in Danish pig herds

By Charlotta Löfström (chalo@food.dtu.dk), Gitte Sørensen and Dorte Lau Baggesen

In the end of 2012 one Danish pig herd was found positive for *Salmonella* Choleraesuis. This event was followed by the isolation of *S.* Choleraesuis from three herds during 2013 in January, August and December, respectively. In all herds there were signs of clinical disease. Finding *S.* Choleraesuis was unexpected since it is rarely found in pigs in Denmark and the last isolation was during an outbreak in 1999 [1]. Infections with *S.* Choleraesuis in humans are also very rare in Denmark. The last human case of *S.* Choleraesuis was in June 2012 and since 2000 only six cases has been reported.

At the National Food Institute, Technical University of Denmark, studies were initiated to investigate the possible connection between the infections. PFGE typing showed that the isolates from the three occasions (1999, 2012 and 2013) had different PFGE profiles, suggesting that several introductions of *S.* Choleraesuis to Denmark had occurred. Epidemiological investigations showed that pigs from the herd found positive in 2012 have been delivered to the herds found positive in January 2013, and that isolates from these two herds had the same PFGE profile. Isolates from the two herds infected in the second half of 2013 shared a different PFGE profile. It has not been possible to identify the primary introduction of the infection to the Danish pig herds. This was also the case for the outbreak in 1999/2000 [1]. Apart from the delivery of pigs from one farm to another taking place in December 2012 and January 2013, no new pigs had to our knowledge been brought into the infected herds, ruling out horizontal spread between herds as a source. Other plausible causes include cross contamination from contaminated vehicles during transport, contaminated feed, contact with infected humans and cross contamination from wildlife, but presently there is no clear evidence pointing at any of these sources.

The lack of source identification may have been caused by limitations in the epidemiological information available, but also by an insufficient resolution of isolates by the epidemiological typing methods applied (mainly PFGE and antimicrobial resistance profiles). Future use of methods with higher resolution, such as whole genome sequencing (see chapter 3 for more information), might help in revealing the source in this and other outbreaks.

7. *Salmonella* Typhimurium DT41 in poultry

By Charlotta Löfström (chalo@food.dtu.dk), Ann-Sofie Hintzmann, Gitte Sørensen and Dorte Lau Baggesen

*Salmonella* Typhimurium is one of the serovars most frequently involved in human salmonellosis in Europe [1], including Denmark (Appendix Table A2). Worldwide, poultry and poultry related products have been reported as an important reservoir of *S.* Typhimurium. Due to the successful implementation of an efficient *Salmonella* control program the prevalence of *Salmonella* in poultry in Denmark has been very low for a number of years (Appendix Table A6 and A8).

Despite the low prevalence of *Salmonella* in the Danish poultry production, reoccurring isolations of different *Salmonella* types, particularly *S.* Typhimurium phage type DT41, has been made in broiler breeder flocks over the past decades without identifying a clear source [2]. During the last quarter of 2013 an unusually high number of flocks were found positive for *S.* Typhimurium phage types DT40, DT41 and unspecific phage types (RDNC). Isolates were found in the whole poultry production chain, including hatcheries, breeding flocks for the broiler production line, broiler flocks and at the slaughter house. One DT41 isolate was also found in animal feed, but to our knowledge this feed was not intended for the poultry sector. These DT41 isolates were of particular interest due to the previous history with repeated findings in poultry breeding flocks and the isolates were therefore characterized in more detail using the DNA based typing method, multi locus variable number of tandem repeat analysis (MLVA).

MLVA-results showed that the three isolates, where the phage type could not be determined (RDNC), were related to the DT41 isolates. Based on the MLVA typing the DT41 and the RDNC isolates (41 isolates in total) were split into eight groups. When a maximum divergence at one locus was permitted these could be gathered into four groups. Using this criterion, combined with epidemiological information, a spread of the infection between some of the flocks within a short time could be documented. Furthermore, one subtype of DT41 was found in the whole production pyramid, from broiler breeding flocks to broilers and the poultry slaughter house. The feed isolate was found to be different from the rest of the isolates.

In conclusion, the source of the sudden increase of *S.* Typhimurium DT41 in the poultry production remains unclear, although it could be concluded that a combination of spread within the production pyramid and new introductions had played a role. However, further studies using more discriminatory typing methods to investigate this in more detail are in progress.

8. Online tools - risk assessment models and predictive microbiology

8.1 TRiMiCri: Easy access to risk based microbiological criteria

By Maarten Nauta (maana@food.dtu.dk)

Microbiological criteria (MC) are used to assess the acceptability of food based on the microorganisms found in samples taken from food lots. Traditionally, MCs are defined on the basis of expert knowledge and a general agreement on feasibility. However, with the rise of quantitative microbiological risk assessment, there is an increased interest in making MCs risk based [1]. This means that the effect of implementing specific MCs is evaluated in terms of their effect in terms of decreased consumer health risks. A new type of risk based MC has been proposed in Denmark, when the case-by-case risk assessment was introduced. Instead of a traditional microbiological limit (ML) on the number of samples that is allowed to carry more than a threshold concentration, it applies a limit for the relative consumer risk (RRL) associated with concentrations found in the samples.

The establishment and evaluation of risk based MCs is often considered to be a difficult task, that requires more than average knowledge of risk assessment. In a project financed by the Nordic Council of Ministries (NMDD) and supported by partners from other Nordic countries, National Food Institute, Technical University of Denmark therefore developed a user friendly software “TRiMiCri”. This “Tool for Risk based Microbiological Criteria” aims to facilitate establishment and application of risk based microbiological criteria, with a focus on Campylobacter in broiler meat.

TRiMiCri has three main functionalities:
- Quantitative concentration data found in samples taken from a food lot can be evaluated for compliance against user-defined MCs.
- Semi-quantitative concentration data found in representative samples can be entered to define a baseline risk, that is needed for the evaluation of RRL MCs. This allows the user to apply the Danish case-by-case risk assessment approach for its own situation.
- The expected effect of setting specific microbiological criteria can be evaluated in terms of effect on consumer health risk and the percentage of (potentially costly) non-complying food lots. This can help food safety managers in defining the most suitable microbiological criterion, based on associated health risks.

TRiMiCri, and its tutorial, are freely available via the website [http://tools.food.dtu.dk/trimicri](http://tools.food.dtu.dk/trimicri). The developers are happy to receive feedback on the tool.

8.2 Food Spoilage and Safety Predictor (FSSP) Software

By Paw Dalgaard (pada@food.dtu.dk)

Mathematical models for growth, survival or inactivation of microorganisms can be valuable tools to evaluate safety and shelf-life of food. However, such predictive microbiology models can be difficult to use in practice unless they are included in user-friendly application software such as Food Spoilage and Safety Predictor (FSSP) [1]. This software contains various models to predict the effect of product characteristics and storage conditions on shelf-life and safety of food. The first version of the software was launched as far back as in January 1999 and it is now widely used in 118 countries.

In 2014 a new and expanded version of the FSSP software is launched. FSSP contains new predictive models and new facilities in addition to all the features already available as part of the former version called Seafood Spoilage and Safety Predictor (SSSP), e.g. models to predict the effect of temperature storage conditions on product shelf-life, models for growth of specific spoilage micro-organisms to predict shelf-life of fresh fish and models to predict food safety including histamine formation in marine fin-fish.

New predictive models in FSSP include:

- Growth and growth boundary model for lactic acid bacteria in meat and seafood products. This new model has been extensively validated and it can be used for a wide range of products [2].
- Expanded model to predict the simultaneous growth of lactic acid bacteria and *Listeria monocytogenes* in various meat and seafood products including some mayonnaise based seafood salads.
- Product specific models for the simultaneous growth of lactic acid bacteria and *Listeria monocytogenes* in chilled cottage cheese.
- A generic growth and growth boundary model for any microorganism/food combination where cardinal growth parameter values like the minimum temperature and pH for growth have been determined. This generic model can take into account the effect of various product characteristics and storage conditions. Predictions can be obtained for constant or for dynamic temperatures, pH and lactic acid conditions.

FSSP can for example be used to document if *Listeria monocytogenes* is able or unable to grow in a product [3]. This specific use of the software is described on the Danish Veterinary and Food Administration website (www.fvst.dk, in Danish). In addition, FSSP can be used to facilitate development or reformulation of especially lightly preserved foods.

FSSP is an important tool for the public sector consultancy, teaching and industry advice given by the Predictive Microbiology research group at the National Food Institute, Technical University of Denmark.

FSSP is available for free at http://fssp.food.dtu.dk. To help interested FSSP users benefit from this tool, one-day workshops are organized as indicated on the FSSP homepage or on request to the author.

9. International topics

By Gudrun Sandø (gus@fvst.dk)

9.1 Control of zoonoses in animal populations

9.1.1 EU coordinated monitoring studies

Based on Zoonosis Directive 2003/99/EC and Regulation (EC) No 2160/2003, the Commission can initiate harmonised studies in order to generate comparable prevalence data from all Member States with the purpose of setting common EU targets for the reduction of the pathogens in question. So far, eight such baseline studies have been carried out concerning Salmonella, Campylobacter, Listeria and MRSA. The EU results have been published on the EFSA website (www.efsa.eu), except from the results of the baseline study on Listeria for smoked fish. The Danish results from these studies have been presented in Annual Reports on Zoonoses 2005–2009.

9.1.2 EU harmonised Salmonella surveillance programmes

Based on the results of baseline studies in flocks of poultry, harmonised regulation on targets and surveillance in the poultry production has been laid down by the Commission.

In 2010, the EFSA published a scientific opinion [1] on monophasic S. Typhimurium-like strains in which it was concluded that the monophasic Salmonella strains with the antigenic formula S. 1,4,[5],12:i:- should be treated equal to S. Typhimurium. Subsequently EU regulations on target end criteria set on Salmonella have included these types as well.

According to Regulation (EC) No 584/2008, the EU target at 1% for breeding and fattening turkey flocks positive for S. Typhimurium or S. Enteritidis had to be reached at the end of 2012. This regulation has now been replaced by Regulation (EC) No 1190/2012 laying down a permanent target of maximum 1% positive breeding and fattening turkey flocks. The regulation includes antimicrobial resistance in poultry, pigs and calves (under 1 year) and meat of broilers, pigs and cattle. The monitoring includes antimicrobial resistance in Salmonella, Campylobacter jejuni, E. coli and from the table egg and broiler production lines.

In Denmark, one rearing flock from the broiler production was positive with S. Typhimurium DT41 in 2013 (Appendix Table A6 and A8).

The EU baseline study on table egg laying flocks carried out in 2004 showed large differences in the prevalence between Member States. Therefore, Member States specific targets were set either as an annual 10–40% reduction of positive adult flocks dependent on the prevalence of positive adult flocks in the Member State the previous year or a maximum of 2% adult flocks positive (Regulation (EC) No 1168/2006). The target was set for S. Typhimurium and S. Enteritidis and had to be reached at the end of 2010. This regulation has been replaced by Regulation (EC) No 517/2011 laying down permanent targets for the reduction of Salmonella in laying flocks. The new regulation maintains the previous targets. For Denmark, the target is a maximum of 2% adult flocks positive for S. Typhimurium (including the monophasic S. 1,4,[5],12:i:- strains) and S. Enteritidis. The prevalence in Denmark has been lower than 2% since 2004. In 2013, four flocks were positive for the target serotypes (One flock with S. Enteritidis and three flocks with S. Typhimurium) (Appendix table A6).

In broiler flocks of Gallus gallus, the target of maximum 1% flocks positive for S. Typhimurium and S. Enteritidis had to be reached at the end of 2011 according to Regulation (EC) No 646/2007. This regulation has been replaced by Regulation (EC) No 200/2012, which maintains the previous target at 1% including the monophasic S. 1,4,[5],12:i:- strains. Denmark has had intensive Salmonella control programmes since the 1990’s and the target of 1% was reached in 2000. In 2012, 0.5% of broiler flocks was positive with S. Typhimurium including the monophasic S. 1,4,[5],12:i:- strains (Appendix Table A8).

9.2 Antimicrobial resistance

The Commission has implemented a harmonised monitoring of antimicrobial resistance within the EU from 2014. The decision is based on a recommendation from the European Food Safety Authority (EFSA). The harmonized monitoring of antimicrobial resistance is implemented for poultry, pigs and calves (under 1 year) and meat of broilers, pigs and cattle. The monitoring includes antimicrobial resistance in Salmonella, Campylobacter jejuni, E. coli and...
ESBL in *Salmonella* and *E. coli*. It is optional for Member States to monitor antimicrobial resistance in enterococci and *Campylobacter coli*. The samples will be collected during a two-year rotation period. In 2014 poultry will be sampled and in 2015 pigs and calves will be sampled. The sampling strategy is harmonised to ensure comparable results between Member States. The idea is that the knowledge gained from the monitoring will raise awareness of the potential antimicrobial resistance problems in the individual Member States and thus lead to increased problem solving.

### 9.3 Microbiological criterion for verotoxin-producing *E. coli* in sprouts

In July 2013, four legal acts and a guidance document on different aspects of production of sprouts came into force. These new provisions included among other things a new microbiological criterion for verotoxin-producing *E. coli* in sprouts. See more in Annual Report on Zoonoses 2012.
10. Surveillance and control programmes

The collaboration between national and regional authorities, the industry and non-governmental organizations is presented in Figure 10.1. According to the Danish legislation, 41 infectious diseases are notifiable in Denmark. An overview of the notifiable and non-notifiable human and animal diseases presented in this report is provided in Appendix Table A29 and Table A30, respectively, including reference to the relevant legislation.

10.1 Surveillance of human disease

Information on human cases due to zoonotic pathogens presented in this report is reported to Statens Serum Institut through different channels depending on the disease:

- Notifiable through the laboratory surveillance system: Salmonella, Campylobacter, Yersinia, Verotoxin-producing E. coli (VTEC) and Listeria.
- Individually notifiable zoonotic pathogens: Chlamydia psittacci (ornithosis), Leptospira, Mycobacterium, Bovine Spongiform Encephalopathy (BSE) prions (var. Creutzfeldt-Jakob Disease), Verotoxin-producing E. coli (VTEC) and Lyssavirus (rabies).
- Non-notifiable zoonotic pathogens: Brucella, Cryptosporidium, Echinococcus, Toxoplasma and Trichinella.

In Denmark, the physicians report individually notifiable zoonotic diseases to the Danish Health and Medicines Authority and the Department of Infectious Disease Epidemiology at Statens Serum Institut. Physicians send specimens from suspected cases to one of the clinical microbiology laboratories depending on the geographical region. Positive cases diagnosed by a clinical microbiological laboratory are reported through the laboratory surveillance system to the Unit of Gastrointestinal Infections at Statens Serum Institut. The laboratories must report positive results to Statens Serum Institut within one week. Furthermore, all Salmonella and VTEC isolates are sent to the reference laboratory at Statens Serum Institut for further sero- and genotyping. The results are recorded in the Register of Enteric Pathogens maintained by Statens Serum Institut. Positive cases are reported as episodes, i.e. each patient-infectious agent combination is only recorded once in any six-month period. Overviews of results from the Register of Enteric Pathogens are presented as follows:
- All laboratory confirmed human cases are presented in Appendix Table A2.
- VTEC O-group distribution in humans is presented in Appendix Table A3.
- The Salmonella serovar distribution is presented in Appendix Table A5.

Figure 10.1. Overview of the monitoring and outbreak investigation network for reporting infectious pathogens in humans, animals, foodstuffs and feedstuffs in Denmark, 2013

Source: Danish Zoonosis Centre, National Food Institute
10.2 Outbreaks of zoonotic gastrointestinal infections

In Denmark, local and regional foodborne outbreaks are typically investigated by the Food Control Offices in collaboration with the medical officers at the Danish Health and Medicines Authority, and the regional clinical microbiology laboratories. Larger regional and national outbreaks are investigated by Statens Serum Institut, the National Food Institute, Technical University of Denmark, and the Danish Veterinary and Food Administration in collaboration. These institutions may also aid in the investigation of local outbreaks. Representatives from these institutions meet regularly in the Central Outbreak Management Group to discuss surveillance results, compare the reported occurrence of zoonotic agents in animals, food, and feedstuffs with that in humans, and coordinate the investigation of outbreaks. The formal responsibility of investigating food- or waterborne outbreaks is currently divided between three ministries based on the outbreak source: the Ministry for Interior and Health for infectious diseases; the Ministry of Food, Agriculture, and Fisheries for foodborne and animal related diseases; and the Ministry of the Environment (along with the municipalities) for waterborne diseases.

Outbreaks may be detected in various ways. Individuals who experience illness related to food intake in settings such as restaurants or work place cafeterias may report these incidents directly to the Food Control Office. General practitioners and hospitals are obliged to report all suspected water- and foodborne infections to the Danish Health and Medicines Authority and to Statens Serum Institut. Clusters of cases may also be noted in the laboratory or identified at Statens Serum Institut through the laboratory surveillance system of gastrointestinal bacterial infections or through subtyping of bacterial isolates from patients.

A list of verified outbreaks (not including household outbreaks) reported to the Food- and waterborne Outbreak Database (FUD) are presented in Appendix Table A4 and some of the outbreaks from 2013 are outlined in Chapter 2.

10.3 Surveillance and control of animals and animal products

Salmonella surveillance and control programmes for poultry, pigs, and cattle are presented in Appendix Tables A31-A36. Sample analysis is performed at authorized private laboratories, the Danish Food and Veterinary Administration laboratory, the National Food Institute, and the National Veterinary Institute at Technical University of Denmark. Salmonella isolates are forwarded to the National Food Institute for serotyping, some isolates are also phage- and genotyped as well as tested for antimicrobial resistance. An overview of the methods used for subtyping is presented in Appendix Table A37.

Overviews of results from surveillance and control of Salmonella are presented as follows:

- Results from the Table egg production are presented in Appendix Tables A5-A7.

---

The new human microbiology database - MiBa

By Luise Müller (lum@ssi.dk)

In 2008, Statens Serum Institut took the initiative to establish a nationwide database with the aim to enable real-time surveillance of communicable diseases and microorganisms as well as provide nationwide access for healthcare personnel to microbiology reports [1]. The database was entitled the Danish Microbiology Database (MiBa) and the establishment and management has been a collaborative process between departments of clinical microbiology at the hospitals (DCM) and Statens Serum Institut. MiBa is mainly financed by a grant from the Danish Ministry of Health from 2009. MiBa is a national database that receives copies of reports from all DCM. The key principle is the simultaneous submission to MiBa of an electronic copy every time a new or updated report is sent from a DCM to the general practitioner or hospital department that requested the test. Since January 2010, copies of all reports submitted by Danish DCMs have been transferred to MiBa. By December 2013, approximately 11 million reports had been uploaded and there were an increasing number of accesses, where health-care employees look up reports in the database, reaching more than 30,000 accesses per month. So far the nationwide sharing of data in MiBa has been a success and has already proved very useful e.g. in the surveillance of influenza and other respiratory infections [2]. The full benefits of a timely and complete surveillance system are still to be experienced. Finally, it is expected that MiBa will provide numerous opportunities for national surveillance of zoonoses in humans also for those that are not currently notifiable [1].

• Results from the broiler production are presented in Appendix Tables A5 and A8.
• Results from the duck and turkey productions are presented in Appendix Table A5 and A9.
• Results from the pig production are presented in Appendix Tables A5, A13 and Figures A1-A3.
• Results from the cattle production are presented in Appendix Tables A5, A14-A15 and Figure A4.
• Results from the feeding stuff production are presented in Appendix Tables A18-A19.
• Results from the rendering plants are presented in Appendix Table A20.
• Results based on suspicion of diseases in pets, zoo animals and wild life are presented in Appendix Table A22-A23.

Overviews of results from monitoring of *Campylobacter* are presented as follows:
• Results from the broiler production are presented in Appendix Tables A10-A11.
• Results based on suspicion of diseases in pets, zoo animals and wild life are presented in Appendix Table A22-A23.
• Results on the relative distribution of *Campylobacter* species in broilers, pigs and cattle are presented in Appendix Tables A12 and A16.

Pig and cattle carcasses are screened for *Mycobacterium* and *Echinococcus* during meat inspection at the slaughterhouse. Although Denmark is assigned as a region where the risk of *Trichinella* in domestic swine is negligible, all slaughter pigs are still examined for *Trichinella* at slaughter as well as wild boars, and horses slaughtered for human consumption. In addition, boars and bulls are tested for *Brucella* and bulls are tested for *Mycobacterium* at semen collection centres. All positive results for notifiable infectious diseases are reported to the Danish Veterinary and Food Administration. Results are presented in Appendix Table A13-A14.

Results from the surveillance for *Bovine Spongiform Encephalopathy* (BSE) in cattle, *Transmissible Spongiform Encephalopathy* (TSE) in sheep/goat are presented in Appendix Tables A24-A26.

Results from the monitoring of *Coxiella burnetii* (Q fever) in cattle are presented in Appendix Table A14.

Results based on suspicion of diseases with *Chlamydia psittaci*, *Cryptosporidium*, *Trichinella*, classical rabies and European Bat *Lyssavirus* in zoo animals, pets and wild life are presented in Appendix Table A22-A23.

### 10.4 Official testing of zoonotic pathogens in foodstuffs

In Denmark, control of zoonotic microorganisms in foodstuffs is mainly carried out as projects which are coordinated at the central level of the Danish Veterinary and Food Administration. Sampling and testing are carried out with the following purposes:
- To verify that food business operators comply with microbiological criteria laid down in the legislation
- To verify the microbiological safety of food for which no microbiological criteria are laid down at EU Community level.
- To monitor the effect of established risk management procedures in order to evaluate if these provide the desired results or need to be reconsidered.
- To generate data for the preparation of risk profiles and risk assessments to support microbial risk management
- To discover emerging problems with microbiological contaminants.

Appendix Table A27 provides information on the centrally coordinated studies conducted in 2013. An overview of these results presented in this report is found in table A27.

For further information consult the website of the Danish Veterinary and Food Administration, [www.fvst.dk](http://www.fvst.dk).

### New action plans

**New action plan on Campylobacter in broilers**

*By Gudrun Sandø (gus@fvst.dk)*

The *Campylobacter* action plan 2013 - 2016 was adopted in spring 2013. This is the second *Campylobacter* plan, and it was developed during 2012 by the Danish Agriculture & Food Council, the Danish Broiler Association, the National Food institute and the National Veterinary Institute at Technical University of Denmark, and the Danish Veterinary and Food Administration.

The action plan covers initiatives in the broiler production at farm level as well as at the slaughterhouse, information to consumers, and as a new element it also covers sources and routes of transmission other than from the broiler production. Targets have been set in the broiler production: The prevalence of positive flocks shall be reduced by 20% by 2016 compared to the level in 2012. The target for fresh broiler meat at the slaughterhouses is formulated as a reduction of the relative risk compared to the level in 2012 and depends on the prevalence as well as the concentration of *Campylobacter* in fresh broiler meat. By the end of 2014 and 2016 the relative risk should be reduced by 25% and 50%, respectively.

The content of the plan and the background for it is described in more detail in Annual Report 2012. Development and target achievement will be evaluated on a yearly basis. The report is available at the Danish Veterinary and Food Administrations website [www.fvst.dk](http://www.fvst.dk) (in Danish).
New action plan on *Salmonella* Dublin in cattle

By Gudrun Sandø (gus@fvst.dk) and Erik Rattenborg

The action plan against *Salmonella* Dublin in cattle was adopted in 2008. The overall aim was to eliminate *Salmonella* Dublin from the cattle production by the end of 2014. As the reduction in the occurrence of seropositive herds did not progress as expected, new initiatives was agreed on in 2013. The initiatives were outlined by the Knowledge Center for Agriculture, Cattle, Department of Large Animal Sciences at the University of Copenhagen, The National Food Institute and the Danish Veterinary and Food Administration.

The new initiatives include classification of regions in Denmark into high prevalence and low prevalence regions. There are restrictions on relocations of animals between regions with different status. Furthermore all positive herds are obliged to initiate herd specific control measures. The provisions are laid down in order no. 954 of 13th of July 2013 on *Salmonella* in cattle. The new aim is to eliminate *Salmonella* Dublin from the cattle production by the end of 2016. The action plan and the new initiatives are described more detailed in chapter 5.

New action plan on *Salmonella* in pigs

By Gudrun Sandø (gus@fvst.dk)

The first action plan against *Salmonella* in pigs and pork was drawn up in 1995. The fourth action plan expired by the end of 2013 and the fifth plan for the period 2014-2017 was adopted in December 2013. The plan was prepared by the Danish Agriculture & Food Council, the Danish Butcher Association, the Danish Meat and Research Institute, the National Food Institute, and the Danish Veterinary and Food Administration.

A technical working group and a steering committee are continuously following up on the action plan, and in 2012 the technical working group evaluated the ongoing fourth action plan and the development in the occurrence of *Salmonella* in herds, slaughter pigs, on carcasses and in humans. The evaluation showed, among other things, that the prevalence of infected slaughter pigs has increased markedly since 1998. Especially the prevalence of pigs infected with *S*. Derby but also the prevalence of pigs infected with *S*. Typhimurium including the monophasic types had increased. The target for the forth action plan was to reduce the carcass prevalence to 1.0% *Salmonella* by the end of 2013. This target was not reached as the prevalence for 2013 was 1.3%.

The target for the new plan is to reach a prevalence of 1.0% *Salmonella* at carcass level in 2014, and to maintain this low prevalence throughout the period (2014-2017).

The following issues have been examined and described in the report on the fifth action plan:

- The background for the increase of *Salmonella* in herds
- The significance of the increase in herds on the prevalence at carcass level
- Hygiene monitoring as a tool at the slaughter houses
- Transmission of infection from pigs, manure and offal

A substantial part of the increase in the proportion of positive herds is caused by live trade of infected pigs. Since 2010 all herds are categorized as *Salmonella* positive or negative, and purchasers are obliged to inform buyers on the status of the herd. However, *Salmonella* is not the only factor of interest when purchasing pigs, and farmers might choose to buy pigs from known *Salmonella*-infected herds because of other characteristics important for the pig producer. The typical herd size and structure has changed in the period since the first action plan was adopted as herds are becoming larger and more specialized. This leads to more purchases and a higher risk of introducing *Salmonella* into the herd. The use of finely ground feed has increased, and this can also lead to increased *Salmonella* prevalence, as it affects gut health.

An increased level of *Salmonella* in the herds leads to a higher risk of contaminated carcasses, but in the period 2001-2012 the slaughterhouses have been able to take the necessary hygiene precautions to manage the increased herd prevalence without increases in carcass prevalence.

To further strengthen and support the hygiene at the slaughterhouse, tools will be developed based on analysis of the registration of contamination at the slaughter line and results of the *E. coli* monitoring. The tools shall contribute to prevent high prevalence of *Salmonella* in the meat. Furthermore, the criterion for intensified *Salmonella* intervention at slaughterhouse level will be included in the yearly evaluation of the plan. The intensified *Salmonella* intervention is imposed on a slaughterhouse, if the 12-months prevalence of *Salmonella* in carcasses is 2 % or above in 4 of 6 consecutive months.

The plan contains recommendations on good practice that can reduce the risk of spread of infection from pigs to other livestock and crops, directed at farmers and growers. In 2014 the Danish Veterinary and Food Administration will also examine the prevalence of *Salmonella* in organically grown vegetables, as the use of manure as fertilizer, poses a risk for transmitting *Salmonella* to crops.

The development and target achievement will be evaluated on a yearly basis. The report on the fifth action plan is available at the Danish Veterinary and Food Administrations website www.fvst.dk (in Danish).
## Trends and sources in human salmonellosis

Note: (imp)= imported product

a) In addition to the above mentioned outbreaks, one household outbreak (FUD 1318) with 2 persons involved was registered in 2013. The outbreak was suspected to have been caused by *C. perfringens* in a beef product containing herbs and spices cooked in the household not paying sufficient attention to the duration of the cooling process after preparation.

b) 12 of the 22 cases in FUD1245 had disease onset in 2012.

a) Including samples from boars (examined at pre-entry, every 18 month, and prior to release from semen collection centres) (15,918 samples), samples collected in connection with export (20,404 samples), import (16 samples) or diagnostic samples (115 samples). 5-8 ml blood samples were analysed using either the SAT, RBT, CFT or ELISA methods.
b) Sampling is based on suspicion of leptospirosis due to increased abortions or other reproductive problems in a herd. Samples are investigated using immunofluorescence techniques.
c) See Table A37 for description of the Salmonella surveillance programme.
d) Data are from December 2013. Slaughter pig herds monitored using serological testing of meatjuice samples collected at slaughter.
e) Includes herds belonging to level 2 and 3 only.
f) Swab samples from four designated areas of the half-carcass were collected at the slaughterhouse after min. 12 h chilling. Sample size is 4x100 cm². Samples from five animals were pooled, except at slaughterhouses where 50 pigs or less were slaughtered per month, in which case samples were analysed individually.
g) When estimating the prevalence of Salmonella, both the loss of sensitivity and the probability of more than one sample being positive in each pool are taken into consideration. A conversion factor has been determined on the basis of comparative studies, as described in Annual Report 2001.
h) Coecum samples are randomly collected from slaughter pigs at slaughter.
i) Samples collected from slaughter pigs at slaughter were examined using the method described in Directive 2075/2005/EEC. In 2007, Denmark achieved official status as region with negligible risk of Trichinella, according to EU Regulation (EC) No 2075/2005.
j) Slaughter pigs were examined by meat inspectors at slaughter.

<sup>a</sup> Denmark has been declared officially brucellosis free since 1979. The last outbreak was recorded in 1962. Including samples from bulls (examined at pre-entry, every year, and prior to release from semen collection centres), samples collected in connection with export, import or diagnostic samples. 5-8 ml blood samples were analysed using either the SAT, RBT, CFT or ELISA methods.

<sup>b</sup> Denmark has been declared officially tuberculosis free since 1980. The last case of TB in cattle was diagnosed in 1988.

<sup>c</sup> Analysis using the tuberculin test. Including samples from bulls (examined at pre-entry, every year, and prior to release from semen collection centres) and samples collected in connection with export.

<sup>d</sup> Bulk tank milk samples taken for diagnostic testing and analysed using an ELISA method.

<sup>e</sup> Serum samples taken for diagnostic testing (76 samples, 18 pos), export (175 samples, 1pos) and breeding (11 samples, no pos) and analysed using an ELISA method. An additional 8 samples from placenta was analysed using the FISH method, none were positive.

<sup>f</sup> See Table A35 for description of the surveillance programme. Swab samples from four designated areas of the half-carcass were collected at the slaughterhouse after min. 12 h chilling. Sample size is 4x100 cm<sup>2</sup>. Samples from five animals were pooled, except at slaughterhouses where 50 cattle or less were slaughtered per month, in which case samples were analysed individually.

<sup>g</sup> When estimating the prevalence of *Salmonella*, both the loss of sensitivity and the probability of more than one sample being positive in each pool are taken into consideration. A conversion factor has been determined on the basis of comparative studies, as described in Annual Report 2001.

<sup>h</sup> Slaughtered cattle were examined by the meat inspectors at slaughter.

<sup>i</sup> Caecal content are tested from one animal per herd, collected at slaughter (DANMAP programme). A 25 g faecal sample from one slaughter calf per herd is examined using overnight enrichment, immunomagnetic separation method and plating on CT-SMAC plates for O157.

b) The *Salmonella* prevalence in each batch is based on the proportion of positive pooled samples (12 pools per batch) and number of subsamples per pool. Only results for batches subjected to risk assessment have been included.

c) Calculated as the risk relative to a batch of the same size with a mean prevalence (weighted average in Danish and imported meat) of *Campylobacter* or of a *Salmonella* type with an average impact to cause human infection.

\(^{a}\) Order no. 954 of 10/07/2013 as amended. In 2013, the programme for eradication of *Salmonella* Dublin from the Danish cattle production was intensified. This implies regionalisation of the country according to prevalence and compulsory eradication plans in Level 2 herds.

\(^{b}\) Herd levels based on serological testing (blood and milk):
Level 1: Herd assumed free of infection based on bulk tank samples (milk producing herd) or blood samples (non-milk producing herd or milk producing herd assumed free of infection).
Level 2: Herd not assumed free of infection.
Level 3: Herd infected based on culture and clinical signs.
\(^{c}\) No samples are taken, if the herd has been tested for S. Dublin within the last 180 days or 8 samples have been tested within the last 24 months.
\(^{d}\) Number of samples equals total number of animals in the herd minus 2 (max. 8 animals, min. 4 animals).
