Probing Spin-Vibronic Dynamics Using Femtosecond X-ray Spectroscopy†

T.J. Penfold, a M. Pápai, b,c; T. Rozgonyi, d K.B. Møller b and G. Vankó c

Ultrafast pump-probe spectroscopy within the X-ray regime is now possible owing to the development of X-ray Free Electron Lasers (X-FELs) and is opening new opportunities for the direct probing of femtosecond evolution of the nuclei, the electronic and spin degrees of freedom. In this contribution we use wavepacket dynamics of the photoexcited decay of a new Fe(II) complex, [Fe(bmip)3]2+ (bmip=2,6-bis(3-methyl-imidazole-1-ylidine)pyridine), to simulate the experimental observables associated with femtosecond Fe K-edge X-ray Absorption Near-Edge Structure (XANES) and X-ray Emission (XES) spectroscopy. We show how the evolution of the nuclear wavepacket is translated into the spectroscopic signal and the sensitivity of these approaches for following excited state dynamics.

1 Introduction

To observe, understand and exploit the simultaneous evolution of nuclear, electronic and spin degrees of freedom on the atomic scale of time, i.e. femtoseconds, is a great challenge with far reaching implications. This is especially pertinent for our understanding of processes occurring within electronically excited states. Metal organic complexes are excellent model systems to study the correlation between these fundamental degrees of freedom1, but are also of significant interest in their own right due to often remarkable photophysical behaviour and versatility2,3. Indeed after photoexcitation, these molecular complexes may undergo any of a plethora of important phenomena including radiative (fluorescence and phosphorescence) decay, non-radiative intramolecular relaxation processes, such as internal conversion (IC) intersystem crossings (ISC, i.e. a spin change) and intramolecular vibrational redistribution (IVR). Most of these processes are accompanied or driven by structural changes occurring as the nuclei adapt to the new electronic structure. Consequently, the relative fraction of these pathways can often be manipulated by modifying the chemical composition4 or by an external perturbation5.

Besides the study of fundamental photophysical processes, transition metal complexes have also gathered significant attention owing to potential applications, such as photosensitisers in photovoltaics or photocatalysts6,7. At the heart of such applications are the photoactive metal-to-ligand charge transfer (MLCT) states. The importance of these states has meant that Fe(II) complexes are generally considered inappropriate as their MLCT states are typically very short lived8,9 owing to the presence of low-lying metal centered (MC) states10. However, Liu et al.11 recently demonstrated that by exploiting the strong field effects of NHC ligands to create [Fe(bmip)3]2+ (bmip=2,6-bis(3-methyl-imidazole-1-ylidine)pyridine), as shown in Figure 1a, it was possible to destabilise the MC states and significantly increase MLCT lifetime. Using ultrafast transient absorption they reported a 1MLCT→3MLCT conversion of ~100 fs, no population of a high spin 5T2 state and a 3MLCT lifetime of ~9 ps11.

Our understanding of these ultrafast processes within metal organic complexes has increased enormously with the emergence of femtosecond pump-probe spectroscopies, and the rapid development within this area has made it possible to tackle increasingly complicated dynamical processes. This complexity provides a strong driving force for combining complementary spectroscopic techniques to resolve a full understanding of excited state dynamics. However, until recently this spectroscopic toolkit has not included techniques within the short wavelength regime12. In particular ultrafast X-ray experiments, made possible by the advent of X-ray Free Electron Lasers13,14 and which are beginning to provide complementary information about a wide range of interesting systems8,15–18.

Advancements in experimental techniques also call for development of theoretical methodologies. In terms of ultrafast X-
ray spectroscopy, this means going beyond simulations of metastable states\textsuperscript{19} and requires accurately including excited states dynamics with nonadiabatic effects. Recently, Capano \textit{et al.} applied quantum dynamics simulations of a prototypical Cu(I)-phenanthroline complex, [Cu(dmp)\textsubscript{2}]\textsuperscript{+} (dmp = 2, 9-dimethyl-1,10-phenanthroline)\textsuperscript{20,21} to simulate femtosecond X-ray spectroscopic signals\textsuperscript{22}. Using realistic experimental parameters they also derived the anticipated signal strengths. This showed that it would be possible to resolve the fine spectral details associated with wavepacket dynamics within realistic experimental acquisition times. Indeed, this was recently confirmed experimentally by Lemke \textit{et al.}\textsuperscript{23} for [Fe(bipy)\textsubscript{3}]\textsuperscript{2+}. In addition, the time-resolved Extended X-ray Absorption Fine Structure (EXAFS) signals were shown to be very effective for probing the width as well as the position of the wavepacket and therefore will provide strong insight into the dynamics associated with vibrational cooling. In this contribution we extend our recent quantum dynamics simulations of [Fe(bmip)\textsubscript{2}]\textsuperscript{2+}\textsuperscript{24} to predict femtosecond X-ray spectroscopy, and in particular the experimental observables associated with X-ray Absorption Near Edge Spectroscopy (XANES) and X-ray Emission (XES). This combination provides insight into structural, electronic and spin dynamics of the 1\textsuperscript{MLCT} and 3\textsuperscript{MC} states. The implications of these simulations on future studies of molecular photophysics at X-FELs is also discussed.

2 Methods and Computations

2.1 Vibrionic Coupling Hamiltonian

The potential used in the present work is based upon the Vibrionic Coupling Hamiltonian model\textsuperscript{25} and has been described in detail in ref.\textsuperscript{24}. Briefly, the diabatic basis is fixed by choosing a point at which it is equal to the adiabatic basis (i.e. the coupling is zero), in this case the Franck-Condon point. The Hamiltonian is expanded as a Taylor series around this point \(Q_0\), using dimensionless (mass-frequency scaled) normal mode coordinates:

\[
H = H^{(0)} + W^{(0)} + W^{(1)} + \ldots
\] (1)

The zeroth order term \((H^{(0)})\) is the ground state harmonic oscillator approximation. The zeroth order coupling matrix \((W^{(0)})\) contains the adiabatic state energies at \(Q_0\). The first order linear coupling matrix elements are written:

\[
W^{(1)}_{ij} = \sum \alpha \Phi_i(Q_0) \frac{\partial H_{\alpha \beta}}{\partial Q_\alpha} \Phi_j(Q_\beta) Q_\alpha
\] (2)

Here, the on-diagonal elements are the forces acting within an electronic surface and the off-diagonal elements are the nonadiabatic couplings. The expansion coefficients for these terms, and those at higher order are obtained from a fit to the potential energy curves along the most important normal modes \((\alpha)\). Similar approaches have recently been used in the case of Cu(I)\textsuperscript{20,21} and Re(I)\textsuperscript{25} transition metal complexes.

In ref.\textsuperscript{24} we used symmetry rules of the \(D_{2h}\) point group to simplify the determination of nonadiabatic coupling elements. We identified four normal modes, which are most important for describing the excited state dynamics. These are a totally symmetric breathing mode \((\nu_5)\), two antisymmetric stretching modes \((\nu_{11} \text{ and } \nu_{25})\), predominately acting on the Fe-C bonds with symmetry \(b_2\), and another totally symmetric breathing \((\nu_6)\) mode with symmetry \(a_1\), predominantly acting on the Fe-N bonds. \(\nu_6\), whose potential energy curves are shown in Figure 1b, is the dominant vibrational mode of [Fe(bmip)\textsubscript{2}]\textsuperscript{2+} and is used during the calculations of the excited state core-hole spectra.

Although a model including only four nuclear degrees of freedom clearly represents a significant reduction in the dimensionality of the potential, this is consistent with the excited state dynamics of many Fe(II) complexes, whose dynamics are usually well represented schematically using one vibrational coordination. Consequently, although the present Hamiltonian is unable to capture longer time effects, such as vibrational cooling, this component has little influence on the ultrafast dynamics.

The potential energy surfaces of the singlet and triplet states were calculated and fitted separately yielding two sets of spin-free potential energy surfaces. The coupling of the two manifolds to create the spin-vibronic potential energy surfaces was treated as a perturbation to the spin-free potential energy curves and was achieved by including the spin-orbit coupling matrix elements between all of the states considered. The potential energy surfaces were calculated using TD-DFT (B3LYP\textsuperscript{27-30}) within the Tamm-Dancoff approximation (TDA)\textsuperscript{31} and a TZVP basis set as implemented within the ORCA quantum chemistry package\textsuperscript{32}. The SOC matrix elements were computed at the ground state equilibrium geometry using the perturbative approach developed by Wang and Ziegler\textsuperscript{33} as implemented within ADF\textsuperscript{34-36}. A TZP basis set was used for all atoms and scalar relativistic effects were included using the ZORA\textsuperscript{37,38} approximation. All the parameters for the potentials, nonadiabatic and spin-orbit couplings for the model used below are available in ref.\textsuperscript{24}.

2.2 Quantum Dynamics

The excited state wavepacket simulations were performed using the Heidelberg Multi Configuration Time Dependent Hartree (MCCTH) package\textsuperscript{39,40}. In this approach the wavefunction
The computational details for the quantum dynamics simulations are shown in Table 1. These ensured convergence of the dynamics for 4 ps. To initiate the excited state dynamics, the wavefunction in the ground state built using one-dimensional harmonic oscillator functions with zero initial momentum was impulsively excited into the lowest $^1$MLCT state at the Franck-Condon geometry.

### 3 Results

#### 3.1 Photoexcited decay of [Fe(bmip)$_2$]$^{2+}$

Figure 2a shows the population kinetics of the $^1$MLCT and $^3$MC states following excitation into the lowest $^1$MLCT states as obtained using the vibronic Hamiltonian outlined above and detailed in ref. 24. The dynamics are dominated by two main processes. The first is an ultrafast ISC from $^1$MLCT$\rightarrow^3$MLCT, which has a time constant of $\sim$100 fs in excellent agreement with previous experimental observations. The rapid nature of this step is a result of the close energetic proximity of the $^1$MLCT and $^3$MLCT states, which promotes strong mixing and leads to efficient population transfer. Figure 2b shows the population kinetics for which the two MLCT states have been summed together. As mentioned above and discussed in below this is important in the context of the sensitivity of the X-ray spectroscopic approaches used herein.

The dominant dynamics in the context of the present work corresponds to the decay of the $^3$MLCT into the $^3$MC states. Our simulations show two components, a faster one, which dominates the timescale of the present study, especially at early times (<2 ps) and which has a time constant of $\sim$1 ps. This is followed by a slower component consistent with a time constant $\geq$4 ps consistent with ref. 11. This population transfer ($^1$MLCT$\rightarrow^3$MC) step is between two triplet states and therefore can occur through two mechanisms, nonadiabatic or spin-orbit coupling. During the first 1-2 ps, both mechanisms contribute and this gives rise to the initial faster component of the decay dynamics. However at later times the contribution of nonadiabatic coupling is reduced due to a redistribution of population within the $^3$MLCT manifold, and this gives rise to the lower population kinetics. This population transfer is slower than the $^1$MLCT$\rightarrow^3$MLCT transition because the population transfer predominantly occurs away from the crossing point between the $^3$MLCT$^3$MC states, at or near the energy minimum geometry of the $^3$MLCT states. Crucially, the energetic separation of the $^3$MLCT$^3$MC states is >0.1 eV and therefore re-
gardless of the coupling strength, efficient population transfer is difficult.

Finally, previous experimental data \(^{11}\) exhibits a weak oscillatory period close to 300 fs. This oscillatory component is very clearly observed in the wavepacket along \(v_6\) (Figure 2c). These oscillations are stronger than observed experimentally due to the absence of the redistribution of vibrational energy within our model Hamiltonian. However, this does reveal that the principal nuclear dynamics during the excited state decay are dominated by the nuclear motion along one nuclear degree of freedom, in this present case \(v_6\) with a period of 300 fs.

3.2 Femtosecond X-ray Spectroscopy

In this section we translate our quantum dynamics simulations \(^{24}\) into ultrafast X-ray spectroscopic signals. As previously mentioned the X-ray techniques addressed herein are unable to distinguish between the \(^{1,3}\)MLCT states. XANES spectra are sensitive to the formal oxidation state and local geometry around the absorbing atom. Therefore the \(^{1,3}\)MLCT states are differentiated from the ground state and \(^{3}\)MC states due to a shift in the edge position to higher energies arising from the increased formal charge of the Fe following transfer of an electron from the metal to the ligands. As this formal charge of Fe is the same for both the \(^{1,3}\)MLCT states, they are indistinguishable. In contrast, the formal oxidation state of the latter (\(^{3}\)MC) remains the same as the ground state, however its edge position will shift to lower energies owing to the structural change of the state, i.e. bond elongations, as the position of the absorption edge depends inversely on the bond lengths of the atoms that coordinate to the absorbing atom \(^{53}\).

In terms of the XES, sensitivity of the spectrum to spin state derives from the the K\(\alpha\)(2p\(\rightarrow\)1s) and K\(\beta\)(3p\(\rightarrow\)1s) emission through the 2p-3d and 3p-3d exchange integrals of the absorbing atom, respectively \(^{54}\). Given the short range nature of this interaction, the emission can be expected to be insensitive to the electronic properties of the ligand, both the \(^{1,3}\)MLCT will be characterised by the doublet spin state of the Fe, instead of the overall spin state of the complex.

3.2.1 X-ray absorption near-edge structure (XANES)

Figure 3a shows the ground state XANES spectrum of \([\text{Fe(bnip)}_2]^{2+}\). It is characterised by a number of spectral features common to Fe K-edges of similar complexes and whose assignments were discussed in ref. \(^{55}\). The red traces show the difference (i.e. excited - ground state) spectra calculated for the MLCT states at the Franck-Condon geometry and the \(^{3}\)MC state at its optimised geometry. The former (dashed line) bears a strong resemblance to the difference spectrum of the MLCT states of \([\text{Cu(dmp)}_2]^+\) \(^{56}\). In this case the spectrum is dominated by the edge shift and can, to a large extent, be reproduced using a shifted difference spectrum, i.e. energy-shifted ground-state spectrum minus the original ground-state spectrum. A similar situation is expected here, as the structure of the ground and \(^{1,3}\)MLCT states of \([\text{Fe(bnip)}_2]^{2+}\) are very similar and therefore the main change is expected to be an edge shift associated with the change of oxidation state of the Fe. The transient spectrum of the \(^{3}\)MC states is characterised by a shift of the absorption edge to lower energy, owing to the expansion of the first coordination sphere. This spectrum exhibits, as expected, a similar profile to the transient spectrum of the metal centred states of \([\text{Fe(bipy)}_3]^{2+}\) reported in ref. \(^{57}\).

Figure 3b shows the temporal evolution of the transient XANES spectra during the first 2 ps after photoexcitation. At early times the spectrum, as expected from the population kinetics in Figure 2a, closely resembles the transient \(^{1,3}\)MLCT spectrum in Figure 3a. As the dynamics progresses the spectrum begins to exhibit increasing characteristics of the \(^{3}\)MC spectrum. There are also clear 300 fs oscillations in the transient signal, consistent with those observed in the transient absorption study \(^{11,24}\). As assigned above, this corresponds to the wavepacket motion along the \(v_6\) breathing mode \(^{24}\) and consequently it is similar to the widely reported wavepacket dynamics of \([\text{Fe(bipy)}_3]^{2+}\) \(^9\).

Figure 4 shows kinetic traces integrated over four main regions, namely 7119-7121 eV, 7122-7124 eV, 7131-7135 eV and 7136-
7143 eV. The lowest two, which probe the pre- and rising edge of the Fe K-edge spectrum show a monotonic rise largely associated with the population transfer between the $^1\text{MLCT}$ and $^3\text{MC}$ states. This is not the case of the latter two ($7131$-$7135$ eV and $7136$-7143 eV), which are slightly non-linear. Indeed, these actually better reflect the population kinetics shown in Figure 2b. This difference derives from the varying sensitivity of the two regions. The former is most sensitive to the electronic structure, the latter the geometric structure. Indeed, as recently shown by Lemke et al.,$^{23}$ the higher lying resonances in the XANES regions are not only sensitive to the position of the wavepacket, but also to higher moments of the wavepacket distribution, e.g. width. This is consistent with the vibrationally very hot wavepacket in the $^3\text{MC}$ state.

The kinetics of each of the 4 spectral regions are imprinted, to a greater or lesser extent with the 300 fs oscillations associated with the wavepacket dynamics along $\nu_6$. This is least clear in latter two ($7131$-$7135$ eV and $7136$-7143 eV), which is because of the sensitivity of the spectra features to both the position and width of the wavepacket, which somewhat convolute these transient features. These spectral changes associated with these dynamics, once a realistic photolysis yield of $\sim 10\%$ is included, are $\sim 0.01\%$ of the spectral features in the ground state and are therefore similar to those reported in ref.$^{11}$ These are about an order of magnitude smaller than the coherent wavepacket motion reported for $[\text{Fe(bipy)}_3]^{2+}$ in ref.$^{23}$, which is consistent with the transient absorption study of ref.$^{11}$ showing only weak wavepacket oscillations.

### 3.3 X-ray Emission (XES)

Complementary to the XANES spectra presented in the previous section is XES, which provides a direct probe of the electronic structure of the occupied density of states and the spin state of the absorbing atom. The sensitivity of the latter derives from the electron exchange integrals, which is a short range interaction around the absorbing atom. This is highlighted in Figure 5 showing the $K\sigma_2$, $K\beta_1$ and $K\beta_2$ emission spectra for $[\text{Fe(bmip)}_2]^{2+}$ simulated at a distorted geometry along $\nu_6$ where the $^3\text{MLCT}$ is the lowest triplet state. The red trace is the ground state spectrum of $[\text{Fe(bmip)}_2]^{2+}$, the green trace is the lowest triplet state, i.e. a $^3\text{MLCT}$ and the blue trace is $[\text{Fe(bmip)}_2]^{3+}$, i.e. one electron removed from Fe, mimicking its electronic structure after excitation into an MLCT state. Adopting this approximation
assumes the inability of these emission spectra to differentiate between the $^{1}$MLCT and $^{3}$MLCT. As can be seen, for both $K\alpha_{1,2}$ and $K\beta_{1,2}$, this approximation holds, as evidenced by the similarity between the blue and green traces. However, the same cannot be said for $K\beta_{2,5}$ emission. In this case, the direct probing of the occupied molecular orbitals provides strong sensitivity of the electronic structure of the ligands, although this comes at the cost of a significant sacrifice of cross section and therefore experimental acquisition time.

Figure 6a shows the ground state (black) Fe $K\beta_{1,2}$ emission spectrum of [Fe(bmip)$_3$]$^{2+}$ and the transient spectra (red traces) corresponding to the $^{1,3}$MLCT and $^{3}$MC. The former are simulated using the approximation (i.e. [Fe(bmip)$_3$]$^{3+}$) described above, while the latter is simulated using unrestricted density functional simulations in the triplet state. The transient spectra for the $^{1,3}$MLCT states are dominated by a shift of the emission energy associated with the larger nuclear charge on the Fe, in contrast the transient of $^{3}$MC indicates a broader emission as well as a shift to higher energies as observed for [Fe(bipy)$_3$]$^{2+}$.

Figure 6b plots the spectral evolution as a function of time. This shows an increase in the intensity of the main features associated with an increasing population of the $^{3}$MC states, as well as shift of the main positive and negative features to large emission energies as would be expected from Figure 6a. As reported previously in ref. 22 and expected for a core-core transition, these spectra exhibit no signature of the coherent wavepacket dynamics.

4 Discussion and Conclusions

Building on our recent quantum dynamics simulations studying the ultrafast photoexcited dynamics of [Fe(bmip)$_3$]$^{2+}$, in this present work we reinforce the ability of X-ray spectroscopy to reveal fine details about excited state dynamics, including coherent wavepacket motion around the absorbing atom. In addition, the spectral signatures in the XANES region for the two sets of excited states ($^{1,3}$MLCT and $^{3}$MC) are shown to be largely out of phase with each other. Consequently, a change in sign of the transient...
signal provides a clear signature of the switching between the two manifolds. Indeed, this was recently used for [Fe(bipy)$_3$]$^{2+}$, albeit for a significantly shorter time. We also confirm that X-ray emission, with the exception of K$_{\alpha}$, is not an effective approach to retrieve coherent wavepacket motion, and consequently is best suited to probing the character of the electronic structure and spin state of the absorbing atom. However, it is emphasised that the local nature of the electron exchange interaction means that the changes must be associated with those on the absorbing atom and not necessarily the molecule as a whole.

Importantly, the details of the excited state dynamics that would emerge from an experimental study on the present system suggests that in comparison to other time-resolved spectroscopies and especially in comparison to the transient optical absorption study on [Fe(bmip)$_2$]$^{2+}$ reported in ref. The femtosecond X-ray spectroscopic studies are unlikely to shed significantly new insight on the photoexcited decay mechanisms. Here, one should bear in mind that the strength of X-ray spectroscopy is providing a local interpretation around the absorbing atom. Consequently, its use will be most valuable in disentangling the dynamics of complex systems which may exhibit important optically dark states and which can give a large number of broad overlapping bands, obvious examples in this direction are multi-nuclear metal complexes or nanoparticles.

Moving forward, an increasing emphasis should be placed upon obtaining sensitivity to the electronic structure of the ligands via X-FEL XES. The biggest challenge for these experiments is the low number of pulses, which can give a large number of broad overlapping bands, obvious examples in this direction are multi-nuclear metal complexes or nanoparticles.

61 It is noted that at distorted geometries along mode 6, the lowest triplet state is no longer the metal centred state, as exploited in Figure 5. This means an uDFT simulation for the metal centred state is strictly no longer valid. However, the fraction of wavepacket that visits this region of the potential is very small and therefore this has no influence on the transient spectra reported.
