1. Introduction

Optical signal processing holds significant potential for bitrate-transparent processing for e.g. wavelength conversion, phase sensitive amplification and many other functionalities. Much effort has therefore been devoted to identifying attractive material platforms for nonlinear signal processing. Integrated solutions based on waveguides in nonlinear materials such as silicon [1], [2, 3] and silicon-germanium [4], [5] as well as silicon nitride [6] and high index doped glass [7] have all been investigated intensively for e.g. wavelength conversion. Unfortunately, the former two are affected by two photon absorption (TPA) at telecom wavelengths, while the latter two provide lower Kerr nonlinearity. In both cases the result is low efficiency of nonlinear interaction and signal generation. The use of second order nonlinearity in periodically poled lithium niobate [8] (PPLN) has yielded promising results. Integration of PPLN devices with other components is however very challenging as it is very broadband operation of the nonlinear interaction.

In this paper we will discuss the AlGaAs-OI platform which, with proper dispersion and bandgap engineering, is not affected by the limitations mentioned above. We will outline the properties of the platform and key fabrication steps. We will then highlight three key demonstrations of nonlinear signal processing in AlGaAs. Firstly, we will summarize the first demonstration of optical wavelength conversion of 256 QAM data. Secondly we will outline the demonstration of high-performance integrated phase sensitive FWM. Finally, we will discuss high-quality spectral broadening enabling single-source 661 Tbit/s data transmission.

2. The AlGaAs-OI Platform

AlGaAs-OI is an attractive platform for nonlinear optical signal processing. Appropriate bandgap engineering can eliminate two-photon absorption (TPA) at telecom wavelengths (around 1550 nm). This opportunity, combined with the possibility to fabricate high-quality integrated waveguide devices, positions AlGaAs-OI as one of the most promising platforms for integrating nonlinear optical signal processing.

Fig. 1 shows pictures of fabricated AlGaAs waveguides indicating typical dimensions and the structure of the devices. The AlGaAs-OI wafer is prepared by wafer growth, wafer bonding and substrate removal. The nano-waveguides are defined by electron-beam lithography and dry etching using a hydrogen silsesquioxane (HSQ) hard mask [9]. Fig. 1 left shows a SEM image of the waveguide prior to SiO2 over-cladding deposition. The cross-section of the waveguide is 290×630 nm² and the propagation loss 1.5 dB/cm.

Fig. 1. – Left: SEM picture of a fabricated AlGaAsOI nano-waveguide (colored blue for clarity). Right: End-view of a fabricated waveguide after PECVD glass cladding. [9]

The AlGaAs core (n = 3.3) surrounded by insulator cladding (n = 1.5) creates a strong field confinement in the waveguide enhancing the already strong nonlinear Kerr effects in AlGaAs (n2 ≈ 10⁻²⁷ W/m²) [11]. Similar to other integrated platforms, the dispersion can be engineered through careful dimensioning of waveguide cross section.
Inverse tapers [12] and lensed fibers are used in order to increase the coupling efficiency into the waveguide, reaching a coupling loss down to 1.4 dB/facet.

3. 256-QAM wavelength conversion

Fig. 2 shows a summary of the results of optical wavelength conversion of 10 Gbaud 256 QAM data signals using single pump FWM in a 9-mm long waveguide. This constitutes the first demonstration of 256 QAM optical wavelength conversion. It is seen from Fig. 2 (a) that wavelength conversion spanning close to 30 nm can be performed with less than 2 dB penalty in the OSNR required to reach a BER of $2 \times 10^{-2}$ after forward error correction (FEC) [13]. For a given pump power, and thus conversion efficiency, the idler OSNR scales linearly with the input signal power. Fig. 2 (b) and (c) shows the high achievable OSNR after wavelength conversion while Fig. 2 (d) shows a detailed characterization of the trade-off between increased OSNR and increased nonlinear distortion when increasing signal power launched into the waveguide. The increase in OSNR results in an improved pre-FEC BER only up to an input signal power of 9 dBm. Beyond this point self-phase modulation begins to dominate signal performance. A maximum achievable signal quality corresponding to an OSNR after conversion of ~31 dB is found. For higher OSNR values the signal is degraded by nonlinear distortion reducing the signal quality. This is clearly recognized as the minimum of the red curve showing the pre-FEC BER in Fig. 2 (d). To achieve further improvement of the converted signal stronger pump power or higher accumulated nonlinearity in the waveguide is required.

**Phase sensitive FWM**

Phase sensitive FWM is demonstrated in AlGaAs-OI achieving a high phase sensitive extinction ratio of 7.7 dB without the need for any enhancement through polarization filtering [14]. The phase-sensitive response can be observed by measuring the signal power at the output of the waveguide as the input signal phase is varied with respect to the pumps. Fig. 3 (a) shows the configuration of the optical waves for achieving phase sensitive FWM. The wavelength of the signal light is placed halfway between two stronger pumps and the interference with the idler light generated by FWM causes a net interaction of the waves which depends on the phase between signal and pumps.

**Fig. 3 – (a) Phase sensitive FWM for different signal phase $\Phi_s$. (b) Phase sensitive extinction ratio measured at varying total launch powers. (c) Comparison between measured and calculated extinction ratio. Results are adapted from [10].**
Fig. 3 (b) shows the normalized output signal power as a function of the signal phase for different input power levels into the AlGaAs-OI waveguide. The sine-square shape of the curves shows the phase sensitive nature of the process. The phase sensitivity increases with power as the generated idler becomes stronger causing stronger interference with the original signal. This reaches a maximum of 7.7 dB for a total input power of 27.5 dBm. In Fig. 3 (c), the measured phase sensitive extinction ratio is compared to numerical calculations for changing output conversion efficiencies meaning different ratios between signal and idler waves. The numerical results are generated by solving the nonlinear Schrödinger equation using the split-step Fourier method. Consequently, they include contributions from higher-order FWM processes taking place in the waveguide. Good agreement is found between numerical and measured results, indicating that a further increase in conversion efficiency could enable even stronger phase sensitive interaction confirming the great potential of the AlGaAs-OI platform for this application.

661 Tbit/s signal source

Finally, a narrow optical frequency comb seed is spectrally broadened in an AlGaAs-OI waveguide and used as a high-quality signal source for the generation of 661 Tbit/s data (80 ch. WDM, 16 QAM, 40 Gbaud, 30 cores) which is simultaneously transmitted over a single multicore fibre [15]. To accomplish this 10-GHz pulses from a mode locked laser are amplified and launched into the AlGaAs waveguide with a peak power of ~5.6 W (19.3 dBm average power). The strong nonlinearity of the waveguide broadens the spectrum of the light through self-phase modulation as seen in Fig. 4 (a) while maintaining a high OSNR of the individual lines. The OSNR is estimated to be >40 dB at the center of the spectrum (1552 nm) and ~30 dB in the worst part of the equalized spectrum shown in Fig. 4 (b) (1563 nm). This is sufficient to allow all parts of the spectrum to carry polarization multiplexed 16 QAM modulation at 40 Gbaud and be split 30 ways to fully load the 30-core fiber with identically modulated temporally de-correlated data channels.

Fig. 4 – (a) Spectral broadening in AlGaAs waveguide due to SPM. (b) Spectrum after filtering and equalization. Figure is adapted from [15]

All the spectral and spatial channels simultaneously propagating in the fiber were characterized without making any changes to the transmitter. All channels could be detected error free and if the employed FEC is adapted to the channel performance a total net data rate of 661 Tbit/s was received. This is by far the highest amount of data transmitted using the light from a single integrated device and it shows the great potential of the AlGaAs-OI platform for use also in multi-frequency light sources for optical communication.

4. Conclusions

Through a number of record breaking achievements in optical signal processing the AlGaAs-OI platform has been confirmed as one of the most promising technologies for optical signal processing. As device fabrication research advances this platform is expected to significantly impact the role of nonlinear signal processing in communication systems and other high-performance applications.
