In this report, we investigate the possibility of using a commercially available Q-switch pumped Supercontinuum (QS-SC) source, operating in the kHz regime, for ultra-high resolution optical coherence tomography (UHR-OCT) in the 1300 nm region. The QS-SC source proves to be more intrinsically stable from pulse to pulse than a mode-locked based SC (ML-SC) source while at the same time is less expensive. However, its pumping rate is lower than that used in ML-SC sources. Therefore, we investigate here specific conditions to make such a source useable for OCT. We compare images acquired with the QS-SC source and with a current state of the art SC source used for imaging. We show that comparable visual contrast is obtainable with the two technologies is achievable by increasing the readout time of the camera to include a sufficient number of QS-SC pulses. © 2017 Optical Society of America

Ultra-High Resolution Optical Coherence Tomography (UHR-OCT) is a non-invasive imaging modality relying on the principle of Low Coherence Interferometry (LCI). Since its first demonstration, UHR-OCT [1] has constantly been improved through progress in optical sources. Nowadays, ultra-high axial resolution within the micron scale is achievable using mainly Supercontinuum (SC) light sources for visible-OCT or near infrared (NIR)-OCT [2,3]. Other optical sources are also used, such as several combined Super-Luminescent Diodes (SLD) or broadband Swept Sources (SS), but their available bandwidth is smaller than that of SC sources. A common drawback of all broadband sources is their relative complexity and consequent cost, that contributes significantly to the high-price of UHR-OCT systems.

The primary UHR-OCT application field is biomedical imaging, however more and more reports can be found regarding Non-Destructive Imaging (NDI) [4]. Non-Destructive Imaging requirements are different compared to eye or skin imaging. Indeed, while speed is one of the main parameters to consider when imaging in-vivo samples, other aspects, such as optical power, spectral range, and penetration depth are more important for NDI. The SC is the only optical source that can offer a large freedom of wavelength choice compatible with a large bandwidth, while delivering a high spatial coherence and a high optical power.

Supercontinuum generation is the spectral broadening of a high-power laser pulse in nonlinear media, such as silica photonic crystal fibers (PCFs). Commercially available SC sources are based on pumping a PCF (in the anomalous dispersion regime close to the zero-dispersion wavelength) with a high-power picosecond or nanosecond laser. In these conditions, SC generation is initiated by modulation instability, which breaks up the pulse into solitons. As a result of soliton interaction and stimulated Raman scattering, the SC is extended towards longer wavelengths. Such SC generation is known to be noisy [5], and display significant pulse-to-pulse intensity fluctuations [6,7]. Current SC sources used in UHR-OCT are based on mode-locked lasers as the pump source.

SC sources reported so far in UHR-OCT use mode-locked lasers as pump sources. This is due to the many advantages offered by these lasers, namely high peak power and MHz repetition rate operation. In fact, a high repetition rate reduces the noise in the UHR-OCT images [8] due to pulse-to-pulse intensity averaging.

An alternative as a pump laser for SC generation is a Q-switched laser. Q-switched lasers offer longer pulse duration than mode-locked lasers with enough peak power for SC generation due to their high pulse energy. Furthermore, an important advantage of Q-switch technology over mode-locking is the much lower cost.
In this report, we demonstrate that a low cost commercially available SC source using a Q-switched pump laser (QS-SC) (SuperK Compact, NKT Photonics) can be used for UHR-OCT. The pump laser operates at 22.222 kHz with a pulse length of 1.6 ns. This study shows that sufficiently good OCT images can be achieved with the only disadvantage of increase in the exposure time of the camera. We compare this QS-SC to an SC source recommended for OCT, which is based on a mode-locked pump laser (ML-SC) (SuperK Extreme, NKT Photonics) with a repetition rate of 320 MHz and a pulse length of 10 ps. The QS-SC source currently costs less than 15% of the ML-SC price.

The UHR-OCT setup, shown in Fig. 1, is a Michelson interferometer with an ultra-broadband 50/50 directional coupler (DC) splitting the light into a reference arm and a sample arm. The reference arm consists of a reflective collimator (C2 - Thorlabs RCO4APC-P01), a dispersion compensation block (Thorlabs LSM02DC), a variable neutral density filter (ND Filter), and a flat mirror (M1). The sample arm consists of a reflective collimator (C1 - Thorlabs RCO4APC-P01), a set of galvanometer-based XY-scanners (Thorlabs GVM002/M) and a scan lens (OBJ - Thorlabs LSM02) offering a spot size of 11 μm at a wavelength of 1315 nm. The spectrometer is a Cobra 1300 (Wasatch Photonics) with an optical bandwidth from 1070 nm to 1470 nm. To do so, the light from the SC source was filtered using several 10 nm bandpass filters (Thorlabs) stepped in their central wavelengths by 50 nm, then detected by an InGaAs photodiode (Thorlabs - DET08CFC - 800 to 1700 nm, 5 GHz). The pulse train was recorded with a fast oscilloscope (Teledyne LeCroy - HDO9404 - 10 bits resolution, 40 GS/s, and 4 GHz). Figure 3(a) summarizes the measured RIN as a function of wavelength. The QS-SC source has a low RIN, between only 2.5-5 %. In contrast, the ML-SC shows strong fluctuations with a RIN ranging from 10 % to almost 45 % at longer wavelengths. We also observe that both SC sources show an increase of the RIN toward longer wavelengths as previously measured in other studies [6]. Apart from the intrinsic noise of the SC sources, it is important to keep in mind the different repetition rates of the sources. While the QS-SC source operates at a kHz rate, the ML-SC source operates at a MHz rate. A simple calculation shows that the difference in pulse number per spectrometer readout between the two SC sources is very large. Considering a line rate in the kHz regime for the camera, the ML-SC delivers several thousands of pulses per exposure time, while the QS-SC only a few pulses. For
instance, an exposure time of 100 µs corresponds to 32,000 pulses for the ML-SC and 2 to 3 pulses only for the QS-SC. However, it is not simple to estimate the improvement due to such a large repetition rate difference as the RIN is not Gaussian noise.

We now characterize the noise in the OCT images as the noise floor of a depth information profile (A-scan) obtained when blocking the sample arm. This is a standard method where one assumes that the signal from the sample arm is weak and does not contribute to noise. To clearly show the trend between the noise and exposure time we average over 500 A-scans. Figure 3(b) shows the noise floor for both SC sources and 4 different exposure times. Each of the 500 noise floors is a readout of the spectrometer, processed with dark signal and background subtraction, normalization, re-sampling, windowing and finally subject to a FT. When varying the exposure time the signal is kept at a similar level on the camera corresponding to 50 % of the dynamic range (~2000 counts). A few pixels from the noise floor of Fig. 3(b) are discarded, at an axial position of 180 µm, as they correspond to interference between the fiber end reflection in the sample arm and the reference.

A first observation is that the two groups of curves in Fig. 3(b), for the QS-SC and the ML-SC are separated by around 20 dB. In the case of the ML-SC, due to the averaging over a high number of pulses, the system is within the shot noise limited regime at around 100 µs (no improvement is seen in the noise floor from 100 µs to 150 µs exposure time). For the QS-SC, the larger the exposure time the lower the noise floor, suggesting that there is an influence of RIN in the OCT system. This initial observation is confirmed by the sensitivity plots presented in Fig. 3(c). The two groups of curves show a sensitivity difference of 20 dB, which might seem important, especially considering the higher RIN of the ML-SC compared to the QS-SC. But again, the large difference in pulses per readout between the two sources gives the advantage to the ML-SC source when considering OCT applications. Using the sensitivity formula in [10], theoretical shot noise limited sensitivity values of 100, 103, 107, and 109 dB are obtained for exposure times of 20, 40, 100, and 150 µs, respectively, for 4 mW power on the sample. These values assume a coupling back into the fiber of 70 % of the light returning from the sample and a spectrometer efficiency of 80 % (estimated, as we use a commercial spectrometer). The 100 and 150 µs exposure time cases for the ML-SC source are close to the theoretical sensitivity shot noise limited values as expected. The QS-SC sensitivity curves lie 20-25 dB below the shot noise limited regime. An extrapolation of the obtained data suggests that a shot noise limited regime could be foreseen with the QS-SC for an exposure time of around 600 µs. However, a too long exposure time clearly impairs the system framerate. It is noticeable that the 150 µs QS-SC lies only a few dBs below the 20 µs ML-SC case. At 20 µs exposure time the camera line rate is around 40 kHz which is a common readout speed reported in recent literature using InGaAs line-scan camera [11].

Figure 4 displays a set of eight images (B-scan). Each B-scan is a 1 mm (depth) x 2.4 mm (lateral) area made of 500 A-scans with a power on sample of 1.3 mW. All B-scans are displayed using identical black and white levels to encode the dB values into a grayscale. When the shortest exposure time of 20 µs is used, the quality of the B-scans obtained with the Q-switched based SC source is poor, with a low SNR. Vertical black stripes appear due to the fact that the camera is at a line-rate of 41.7 kHz corresponding to the repetition rate of the source. The black stripes represent readouts without any optical pulse. If the exposure time is raised to 40 µs, then the mismatch between source pulse and camera read out is still present but the image quality improves, with clear structural information distinguishable. Finally, when the exposure time is increased to 100 µs or 150 µs, both sources deliver good final image quality with similar axial resolutions and identical distinguishable structural information.
likelihood of saturation of the camera (vertical white stripes) and the occurrence of disturbing events in the image due to autocorrelation terms.

So far, we have tested the QS-SC for NDI UHR-OCT. However, biomedical application is the main target for OCT. Figures 5 and 6 are examples of skin images acquired in-vivo from the hand palm of a healthy volunteer using 4 mW on the sample. The volume dimensions are 500 (A-scans) by 500 (B-scans) by 1024 (depth). These are acquired in 37.5 s for the longest exposure time (150 µs) considered. This time is too long for imaging to be applied to samples in motion, as it is the case with imaging the eye, heart or even skin. For such long exposures, motion correction processing would be required before any volume averaging or any other advanced processing. Using the shortest exposure time of 20 µs, a volume acquisition can be finalized in 5 s, this is however still long for biomedical imaging of organs. Here, to compensate for eventual movement in x and y direction, we have used a handheld probe, which is in contact with the sample except for a small aperture reserved for the optical beam scanning. This restricts the motion along the depth direction only, as the sample is maintained stationary in respect to the x and y directions. Then, the remaining motion in the z-direction can be compensated through conventional algorithms [12], if further volume processing would be considered.

In terms of image quality, conclusions can be drawn similar to those from imaging the IR card above. Figures 5 and 6 confirm that 20 µs and 40 µs are too short exposure times and during such intervals the number of pulses is less than one. As soon as there are a few more pulses per readout, the QS-SC reaches similar image quality the number of pulses is less than one. As soon as there are 20 µs and 40 µs are too short exposure times and during such intervals the number of pulses is less than one. As soon as there are a few more pulses per readout, the QS-SC reaches similar image quality compared to the ML-SC. A difference of 20 % is obtained in the contrast. In the case of the en-face display of Figure 6, the problem of black stripes due to readouts containing no pulses is very important. The images acquired at 20 µs and 40 µs show almost no structural information.

In this study, we demonstrated that a QS-SC can be used for UHR-OCT at 1300 nm. Even though the repetition rate of this source is in the kHz regime, a small increase in the exposure time of the camera can lead to an image quality comparable to state of the art systems. Differences in contrast are observed to be quite low (~20 % less than more standard ML-SC sources). In-vivo images of skin were also demonstrated, though it is important to consider that the long exposure time (seconds to tens of seconds for volume acquisition) demands tracking or compensation procedures. An important advantage of the QS-SC is its lower cost, only 10-15 % of that of the ML-SC conventionally used in UHR-OCT. In addition to the demonstrated operation in the 1300 nm range, the QS-SC source is suitable for operation either at shorter wavelengths (800 nm range) or even at longer wavelengths (1700 nm, 2000 nm range).

**Fig. 6.** Example of 4 mm x 4 mm C-scans extracted from a volume acquired from a healthy volunteer hand palm skin. (a-d): ML-SC based C-scans and (e-h): QS-SC based C-scans. Exposure times 20, 40, 100, 150 µs. (scale bar 1 mm) – (NaN means that the contrast cannot be calculated for the 20 µs QS-SC image due to lack of signal).
