The Geometrical Theory of Diffraction for Axially Symmetric Reflectors

W. V. T. RUSCH, SENIOR MEMBER, IEEE, AND O. SØRENSEN

Abstract—The geometrical theory of diffraction (GTD) (cf. [1], for example) may be applied advantageously to many axially symmetric reflector antenna geometries. The material in this communication presents analytical, computational, and experimental results for commonly encountered reflector geometries, both to illustrate the general principles and to present a compact summary of generally applicable formulas.

I. AXIALLY SYMMETRIC REFLECTOR FOR VECTOR SPHERICAL-WAVE POINT SOURCE ON AXIS

If a point-source feed is located on the axis of an axially symmetric reflector, then only two singly edge-diffracted rays are possible for a distant field point \( P(R, \theta, \phi) \), if \( \theta \neq 0, \pi \) (Fig. 1). These rays are "diffracted" from \( Q_E^+ \), where the plane \( \phi \) intersects the edge on the same side of the \( Z \) axis as the field point, and from \( Q_E^- \), where the plane \( \phi + \pi \) intersects the edge diametrically opposite \( Q_E^+ \) on the opposite side of the \( Z \) axis from the field point.

The geometry of the edge-diffracted ray from \( Q_E^- \) is shown in Fig. 2. (The surface is assumed to be convex.) The ray from the feed to \( Q_E^- \) defines \( \theta_{\text{edg}} \), and the corresponding extreme geometrically reflected ray, when extended back to the \( Z \) axis, defines \( \theta_{\text{edg}} \). These two angles may then be used to define two intermediate angles used in the edge-diffraction notation of

\[
E_d = [E_{d\phi}(\theta, \phi) a_{\phi} + E_{d\phi}(\theta, \phi) a_{\phi}] e^{-jk_R R} \]  
(2)

where the angles and unit vectors for both sets of feeds are defined in the sense indicated in Fig. 1. Then the components of \( E_d \) can be decomposed into contributions from both \( Q_E^+ \) and \( Q_E^- \):

\[
E_{d\phi}(\theta, \phi) = E_{d\phi}^+(\theta, \phi) + E_{d\phi}^-(\theta, \phi), \quad (3a)
\]

\[
E_{d\phi}(\theta, \phi) = E_{d\phi}^+(\theta, \phi) + E_{d\phi}^-(\theta, \phi). \quad (3b)
\]

Considering first the diffracted field from \( Q_E^+ \) (because no transition functions are required for these rays):

and for \( \delta_2 < \theta < \pi/2 \):

\[
D_{\phi} = \begin{cases} 0, & \pi/2 - \delta_2 < \theta < \pi \\ \frac{1}{2\sqrt{2\pi k}} \left[ \frac{1}{\cos(\theta + \delta_2 + \alpha/2)} \pm \frac{1}{\sin(\theta + \delta_2 - \alpha/2)} \right], & 0 < \theta \leq \pi/2 - \delta_2 \end{cases} \]  
(5)

where the upper signs are taken for the soft (\( s \)) coefficient and the lower signs are taken for the hard (\( h \)) coefficient. Notice that

$D_s^-$ is zero in the direction of the surface tangent, $\theta = \pi/2 - \delta$, but $D_h^-$ is not. Slightly modified but principally the same diffraction coefficients for singly edge-diffracted rays may be derived for concave surfaces.

The geometry of the ray diffracted from $Q_E^+$ is shown in Fig. 3. The fields of this ray are given by

$$E_{d+}^+(\theta, \phi) = \left( \frac{E_F(\pi - \theta_{edge}) e^{-jkD_{refl}/2}}{D_{edge}} \right) \left\{ \left( \frac{D_{refl}/2}{\sin \theta} \right) \right\} \cdot \exp \left[ \pm jk \left( 2c + Z_{edge} \right) \cos \theta + \left( D_{refl}/2 \sin \theta \right) \right]$$

(6a)

$$E_{d-}^+(\theta, \phi) = \left( \frac{E_F(\pi - \theta_{edge}) e^{-jkD_{refl}/2}}{D_{edge}} \right) \left\{ \left( \frac{D_{refl}/2}{\sin \theta} \right) \right\} \cdot \exp \left[ \pm jk \left( 2c + Z_{edge} \right) \cos \theta + \left( D_{refl}/2 \sin \theta \right) \right]$$

(6b)

where [1]

$$D^+_h = \frac{- e^{-jk/4}}{2\sqrt{2}k} \left[ F[kL'\alpha(\theta - \delta - \alpha)]/2 \right] \pm \left[ F[kL'\alpha(\pi - \theta - \delta + \alpha)]/2 \right] \sin \left( \theta - \delta + \alpha \right)$$

(7)

$$a(x) = 2 \cos^2 \left( \frac{x}{2} \right) \quad \text{(8a)}$$

$$F(kL) = 2j\sqrt{kL} e^{jkL} \int_{-\pi}^{\pi} e^{-jkx} \mathrm{d}x \quad \text{(8b)}$$

The transition functions $F(kL)$ remove the singularities at the shadow boundary ($\theta = \pi - \theta_{edge}$) and at the reflection boundary ($\theta = \theta_{edge}$). Furthermore,

$$L^1 = \frac{D_{refl}}{\beta_{1}^r} \sin \theta_{edge} \quad \text{(9a)}$$

$$L^2 = \frac{\beta_{1}^r \beta_{2}^r \sin \theta_{edge}}{(D_{refl}/2)} \quad \text{(9b)}$$

where $\beta_1^r$ and $\beta_2^r$ are the principal radii of curvature of the reflected geometrical ray at $Q_E^+$ and $(D_{refl}/2)\sin \theta_{edge}$ is the caustic distance evaluated in the direction of the reflection boundary.

For the point source on the $Z$ axis illuminating the axially symmetric reflector, the resulting single edge-diffracted rays have a caustic at all points on the $Z$ axis. Thus all ray path-lengths $FQ_E^P$ are the same if both $F$ and $P$ lie on the axis of symmetry. Ray optical solutions fail in the neighborhood of these caustics, as, for example, the $\sin \theta$ denominator in the square-root factor of (4) and (6) vanishes. Alternative solutions near caustics are canonical solutions [2], asymptotic solutions [3], [4], and integral solutions [1], [5]. The latter technique consists of replacing the edge-diffracted rays with contributions from equivalent electric and magnetic ring currents lying along the edge:

$$I_{e+} = \frac{-E_F D_1(\phi - \phi'; \pi/2)}{\eta} \sqrt{\frac{8\pi}{k}} e^{-jk/4} \quad \text{(10a)}$$

$$I_{e-} = -H_F D_0(\phi, \phi'; \pi/2) \sqrt{\frac{8\pi}{k}} e^{-jk/4} \quad \text{(10b)}$$

where $E_\phi$ and $H_\phi$ are the edge-tangential incident electric and magnetic fields, $D_1(\phi, \phi'; \pi/2)$ and $D_0(\phi, \phi'; \pi/2)$ are the soft and hard edge-diffraction coefficients, and $\phi, \phi'$ are the angles of diffraction and incidence in the "Ray-fixed" coordinate systems defined by Kouyoumjian [1]. For an arbitrary field point $\phi$ is different at various points on the rim. However, for a field point on axis $\phi$ is constant (at great distances on axis $\phi = \pi/2 - \delta$, furthermore, for this symmetric case $\phi' = \pi/2 + \alpha$).

The most commonly encountered feed function is that of a far-field, $m = 1$, spherical-wave source for which the tangential fields incident on the edge are

$$E_\phi = \frac{d_1(\theta)}{\eta} \frac{e^{-jkD_{refl}/2}}{\rho_{edge}} \quad \text{(11a)}$$

$$H_\phi = \frac{1}{\eta} a_1(\ell_2) \frac{e^{-jkD_{refl}/2}}{\rho_{edge}} \quad \text{(11b)}$$

The easily computed ring current fields then become as follows.

$\theta = 0$:

$$E_{ring} = a_y \left( \frac{D_{refl}/2}{R} \right) \exp \left[ -jk(2c + Z_{edge}) \right] \frac{e^{-jkR}}{R} \cdot \left\{ - \left[ \frac{d_1(\pi - \theta_{edge}) e^{-jkD_{refl}/2}}{\rho_{edge}} \right] \right\}$$

(12a)

$\theta = \pi$:

$$E_{ring} = a_y \left( \frac{D_{refl}/2}{R} \right) \exp \left[ -jk(2c + Z_{edge}) \right] \frac{e^{-jkR}}{R} \cdot \left\{ - \left[ \frac{d_1(\pi - \theta_{edge}) e^{-jkD_{refl}/2}}{\rho_{edge}} \right] \right\}$$

(12b)

Fig. 4. Geometry of four possible edge rays.
\( \theta \) small but nonzero:

\[
E_{\text{ring}} \approx \frac{(D_{\text{refl}}/2)}{4} \exp \left[ jk(2\epsilon + Z_{\text{edge}}) \cos \theta \right] \frac{e^{-jk_{\text{edge}} e^{-jkR}}}{\rho_{\text{edge}}} \frac{1}{R} \cdot \left\{ a_{\phi} \left[-d_{1}(\pi - \theta_{\text{edge}}) \frac{1}{\cos (\theta_{\text{edge}}/2)} \right] - \frac{1}{\sin (\theta_{\text{edge}}/2)} \left[ J_{0}(\beta) + J_{2}(\beta) \right] \cos \theta \right.
\]

\[
- a_{1}(\pi - \theta_{\text{edge}}) \left[ \frac{1}{\cos (\theta_{\text{edge}}/2)} + \frac{1}{\sin (\theta_{\text{edge}}/2)} \right] \cdot \left[ J_{0}(\beta) - J_{2}(\beta) \right] \sin \phi
\]

\[
+ a_{\phi} \left[-d_{1}(\pi - \theta_{\text{edge}}) \frac{1}{\cos (\theta_{\text{edge}}/2)} \right] - \frac{1}{\sin (\theta_{\text{edge}}/2)} \left[ J_{0}(\beta) - J_{2}(\beta) \right] \left[ J_{0}(\beta) + J_{2}(\beta) \right] \cos \theta \cos \phi \]

\( (12c) \)

where \( \beta = k(D_{\text{refl}}/2) \sin \theta \). Equation \( (12c) \) is an approximation in that the changes in \( D_{\epsilon} \) and \( D_{h} \) in equations \( (10a) \) and \( (10b) \) at various points on the rim have been assumed to be second order for relatively small values of \( \theta \).

II. AXIALLY SYMMETRIC REFLECTORS FOR VECTOR SPHERICAL-WAVE POINT SOURCE OFF AXIS

If a point-source feed is located off the axis of the axially symmetric reflector, Fermat's principle reveals that there are a maximum of four possible diffraction points around the rim of the reflector [6]. The situation becomes somewhat less complicated when the point-source feed, the reflector axis, and the observation point all lie in the same plane (taken, for example, to be the \( X - Z \) plane in Fig. 4). Under these conditions, diffraction points 1 and 2 are possible for all possible positions of the distant field point. However, if the field point is on the opposite side of the axis from the source point, then two additional diffraction points 3 and 4 are also possible in the range of \( \theta \) values, \( \theta_1 \leq \theta \leq \theta_2 \) [7] where

\[ \theta_1 = \sin^{-1} \left[ \frac{X_{\text{feed}}}{\sqrt{(D_{\text{refl}}/2 + X_{\text{feed}}^2) + (Z_{\text{edge}} - Z_{\text{feed}})^2}} \right] \]

\[ \theta_2 = \sin^{-1} \left[ \frac{X_{\text{feed}}}{\sqrt{(D_{\text{refl}}/2 + X_{\text{feed}}^2) + (Z_{\text{edge}} - Z_{\text{feed}})^2}} \right] \]

\( \theta_1 \) corresponds to a caustic at infinity form point 2, while \( \theta_2 \) corresponds to a caustic at infinity from point 1. Thus, as \( \theta \) increases from \( \theta_1 \) to \( \theta_2 \), the additional roots 3 and 4 move from 2 to 1. In practice, for typical reflector geometries the range of values from \( \theta_1 \) to \( \theta_2 \) is sufficiently small so that the entire range is covered by radiation from the equivalent ring sources to avoid unrealistically large predicted fields. An example of a multi-caustic region is for values of \( \theta \) between 0.11 and 0.14 deg. However, the simple geometrical theory of diffraction (GTD) two-edge ray description of the field is seen to become unrealistically large outside the multiroot range. The ring-current contribution, on the other hand, is well behaved and very close to the physical optics results over a relatively wide angular range.

III. SURFACE DIFFRACTED RAYS

First-order surface rays will ordinarily not be directly excited by the feed in a reflecting antenna system. However, they may be excited by tangential edge-diffracted rays. An example may be seen in Fig. 2 where an edge-diffracted ray from \( Q_{\text{edge}}^- \) in the direction \( \theta = \pi/2 - \delta_1 \) will tangentially graze the surface. Only the tangential \( H \)-field component will be nonzero in this direction, but the excited surface rays are necessary to provide a continuous field. In most instances, however, the edge-diffracted rays provide sufficiently accurate surface rays.

IV. APPLICATIONS

A. Radiation from Prime-Focus Paraboloid

The Kouyoujian group has used a combination of a single edge-diffracted GTD, equivalent ring-currents, and physical optics to compute the complete radiation pattern of a prime focus paraboloid [8], [9]. The calculated pattern was compared with the experimental results of Afifi, which were measured for a half-paraboloid on a groundplane with a monopole feed at the focus [10]. This experimental arrangement virtually eliminated aperture

Fig. 5. Comparison of PO, GTD, and ring-current fields in multicaustic directions.
exciting surface-diffracted rays. The deep reflector blocking. The vertical polarization eliminated the possibility of eliminating rear spillover. The agreement between the calculated measurement error.

B. Radiation from Hyperboloid with Spherical-Wave Feed at Its External Focus

Results have been obtained for a "focused" hyperboloid using physical optics, geometrical optics, GTD (Keller), and GTD (Kouyoumjian) [11]. The geometrical-optics results are discontinuous at the reflection boundary. The physical optics and Kouyoumjian GTD results agree closely in magnitude and phase, both in the illuminated and shadowed regions as well as in the vicinity of the reflection boundary.

Fig. 6 is a complete H-plane pattern based on GTD. The fields at the reflection boundary at 64 deg and the shadow boundary at 152.4 deg are finite and continuous, and the two axial caustics are computed using the equivalent ring sources. This technique yields slightly different results at the rear axial caustic than the caustic correction factor of Keller [2], which did not yield E-plane-H-plane continuous fields on axis.

Results were also reported in [11] that compare the calculated and measured scattered H-plane patterns from a hyperboloid illuminated by a corrugated horn with its phase center at the hyperboloid's external focus [12]. The GTD results included two edge rays from the reflector and one from the leading edge of the horn on the field-point side of the axis. Equivalent ring currents around both the reflector and horn rims were used for field points near the axis. These GTD results agreed with the measured patterns within the experimental uncertainties.

V. EVALUATION OF FOCUSED EQUIVALENT PARABOLOID USING GTD

The techniques of GTD provide a computational procedure to obtain RF performance data that hitherto was excessively costly in computer time. A prominent example of this is the dual-reflector antenna. Hitherto, it was only possible to analyze dual-reflector systems by integrating over both reflectors. The subreflector in a system of this type generally creates a shaped, rather than a focused, beam and consequently is readily amenable to GTD determination of the scattered field. This rapidly determined scattered field then provides the illumination function for a physical optics integration over the large focused primary mirror.

The equivalent paraboloid is said to provide an accurate technique for the calculation of performance characteristics for Cassegrain and Gregorian systems [13]. GTD provides an accurate and relatively economical technique to verify this assertion quantitatively. For example, in Fig. 7, the aperture efficiency (exclusive of spillover) is calculated for a Cassegrain system with a paraboloid F/D = 0.4 and subreflector diameter/main reflector diameter ratio = 0.25. Diffraction from the subreflector causes the illumination of the main reflector to be tapered. However, this taper is not included in the equivalent paraboloid calculation, and its predicted efficiency is significantly higher, even for subdish diameters as large as 100 wavelengths. Since the edge illumination of the equivalent paraboloid is higher than the actual edge illumination, it generally predicts higher wide side-lobes than actually exist [14].

Relation Between the Radiation Pattern of an Array and the Two-Dimensional Discrete Fourier Transform

S. HAYKIN and J. KESLER

Abstract—A linear wideband array with each element followed by a tapped-delay line may be considered as a two-dimensional digital filter. Accordingly, the radiation pattern of the processor may be expressed as the product of a pair of two-dimensional discrete Fourier transforms (DFT’s).

I. INTRODUCTION

It is well known that z transform relations in linear systems can be used to describe the behavior of linear antenna arrays [1]. The objective of this article is to extend this treatment to a wideband array processor consisting of a linear array, each element of which is followed by a tapped-delay line network [2]. It will be shown that the radiation pattern of such a processor can be expressed as the product of a pair of two-dimensional discrete Fourier transforms (DFT’s).

II. THE INTERPRETATION OF AN ARRAY PROCESSOR AS A TWO-DIMENSIONAL DIGITAL FILTER

A linear antenna array may be viewed as a sampled data system in the sense that the current distribution in the discrete elements of the array may be considered as the sampled values of a continuous function [1]. The equivalent sampling period of

\[ W(z_1,z_2) = \begin{bmatrix} w_{00} + w_{01}z_2^{-1} + w_{10}z_1^{-1} + w_{11}z_1^{-1}z_2^{-1} + w_{N-1,0}z_1^{-N+1} + w_{N-1,1}z_1^{-N+1}z_2^{-1} \end{bmatrix} \]
