Clean, alternative energy carriers will be needed as fossil fuel reserves are depleted. One possible energy carrier under consideration is H$_2$, which can be produced cleanly and renewably if solar or wind energy is coupled to water electrolysis. Unfortunately, the hydrogen evolution reaction (HER) is catalyzed most effectively by Pt group metals\textsuperscript{1} – materials that are expensive and scarce. New materials are needed if this scheme is to ever become viable.

Having studied different metal surfaces and enzymes that catalyze hydrogen evolution, we have found a necessary criterion, a “descriptor”, for high catalytic activity – the binding energy (Gibbs free energy) of atomic hydrogen adsorption must be close to zero.\textsuperscript{1,2} Not surprisingly, the nitrogenase and hydrogenase enzymes – both of which evolve H$_2$ in nature – satisfy this requirement. In an effort to develop solid-state analogues of the enzymatic active sites, theoretical calculations have guided us to MoS$_2$ nanoparticles and Mo$_3$S$_4$ complexes, which were subsequently synthesized and investigated for hydrogen evolution.

Having already confirmed the catalytic activity of MoS$_2$ nanoparticles for hydrogen evolution\textsuperscript{2}, more recently we have aimed to identify relationships between structure and catalytic activity within the MoS$_2$ nanoparticles. In our approach, we combine ultra high vacuum techniques with electrochemical measurements under ambient conditions. MoS$_2$ nanoparticles were first synthesized on Au(111) in ultra-high vacuum, where scanning tunnelling microscopy (STM) was used to investigate their structure, morphology, and surface coverage (Fig. 1). Surface spectroscopy was also employed for chemical characterization. These UHV-prepared samples were then transferred to an electrochemical cell where catalytic activity for hydrogen evolution was measured. By varying particle size and coverage within the sample set, our measurements have established – for the first time – a clear relationship between the structure and catalytic activity of MoS$_2$ nanoparticles.

Bearing in mind the active edge state in MoS$_2$ nanoparticles\textsuperscript{2}, we have looked to other solid-state systems which also mimic the active site within nitrogenase and/or hydrogenase. One candidate material is an aquo, tri-nuclear molybdenum complex, [Mo$_3$S$_4$]$^{4+}$, which we have synthesized following the procedure in reference 3 (see Fig. 2). Our theoretical model predicts these complexes to be active for hydrogen evolution, and to investigate them experimentally we have deposited them as individual, separate entities onto an inert HOPG substrate. We subsequently characterized these catalysts using STM, surface spectroscopy, and electrochemical methods. The supported Mo$_3$S$_4$ complexes demonstrated excellent catalytic activity for hydrogen evolution, just below that of the Pt-group metals, per active site.
