(Received 19 August 2010; revised manuscript received 19 January 2011; published 9 May 2011)

Nanochannel ion transport is known to be governed by surface charge at low ionic concentrations. In this paper, we show that this surface charge is typically dominated by hydronium ions arising from dissolution of ambient atmospheric carbon dioxide. Taking the hydronium ions into account, we model the nanochannel conductance at low salt concentrations and identify a conductance minimum before saturation at a value independent of salt concentration in the dilute limit. Via the Poisson–Boltzmann equation, our model self-consistently couples chemical-equilibrium dissociation models of the silica wall and of the electrolyte bulk, parametrized by the dissociation reaction constants. Experimental data with aqueous KCl solutions in 165-nm-high silica nanochannels are described well by our model, both with and without extra hydronium from added HCl.

I. INTRODUCTION

Nanofluidics and specifically, ion transport through artificial nanochannels, are important for both fundamental scientific studies and for practical biomolecular and energy-based applications [1–3]. Of particular interest is the intricate interplay among surface chemistry, electrokinetics, and fluid dynamics spanning over molecular and continuum macroscopic length scales [4,5]. It has been demonstrated that the electrokinetic properties at this scale have enabled a range of innovations including those for chemical sensing and bioanalytics [6–12], energy harvesting systems, [13–18], and nanofluidic ion transport [19–26], including enrichment, depletion, and rectification effects [27–32].

For many of these applications, characterizing and understanding the conduction properties of electrolyte-filled nanochannels at low salt concentrations (<10^{-3} M) is important, and this raises the question of the role of hydronium ions. It is well known that, under standard conditions, the dissolution of ambient atmospheric carbon dioxide in de-ionized (DI) water leads to the formation of carbonic acid, which, upon reaching chemical equilibrium with the water, gives rise to an inherent concentration of hydronium ions of $\sim 10^{-6}$ M corresponding to pH 5.7. Because hydronium has a uniquely high mobility, a factor of $\sim 5$ higher than common salt ions, in bulk solutions, it is found that hydronium ions begin to dominate the electrical conductivity when the salt concentration is lower than $\sim 5 \times 10^{-6}$ M. Furthermore, hydronium is also known to interact with the confining walls of the electrolyte. For oxide walls, most prominently silica, numerous studies have shown how hydronium affects the electrical properties of the wall-electrolyte interface and leads to a wall surface charge that depends on salt concentration [33–44] including our own recent study [26]. Finally, at sufficiently low salt concentration, this surface charge is found to dominate the conductance of electrolyte-filled nanochannels [8,11,19,24,27,28,32,45]. Given these facts, it is remarkable that the role of hydronium ions is largely unexplored in the literature on nanochannel conductance at low salt concentrations in unbuffered solutions.

The main goal of this paper is to provide such an analysis mainly in terms of theoretical modeling, but also supported by our own experimental validation. Among the dozens of papers published on nanochannel conductance, we have only found a single very recent paper dealing directly with similar modeling [32].

Another motivation for our paper is to explain the appearance of a minimum in the nanochannel conductance as a function of salt concentration, which several groups have observed, but not noticed, see Table I. The minimum, which cannot be explained by depletion effects near the entrances, as this would lead to a decreased conductance at the lowest salt concentration, is found to occur for salt concentrations $\sim 5 \times 10^{-6}$ M, the above-mentioned crossover from salt to hydronium-dominated conductance. The main result of our analysis is that our model predicts such a minimum due to the presence of inherent hydronium ions.
II. MODEL

We consider a long straight nanochannel connecting two large bulk reservoirs. Traditionally, theoretical modeling of ionic transport in such systems is based on the Gouy–Chapman–Stern theory of electrostatic screening by the mobile co- and counterions in an aqueous salt solution of a wall with constant surface charge, coupled to the continuum fluid dynamics equations and, thus, forming the Poisson–Nernst–Planck transport equations [47]. This results in a monotonically decreasing nanochannel conductance as a function of decreasing salt concentration that levels off at a plateau in the dilute limit, as shown in Refs. [19, 24, 28, 45, 46] of Table I and summarized by Fig. 8 in a recent review paper [2]. However, this is in contrast to the observed nonmonotonic conductance graphs with a minimum, seen in Refs. [8, 11, 27] and summarized by Fig. 8 in a recent review paper [2].

Building on our own recently published work [26], we extend these previous buffer/wall dissociation models to low concentration unbuffered electrolyte systems by the addition of two crucial features: First, we account for hydronium ions concentration unbuffered electrolyte systems by the addition of a new variable that represents the concentration of hydronium ions, here denoted as $H^+$ for brevity, from autoprotolysis of water in a recent review paper [2]. However, this is in contrast to the observed nonmonotonic conductance graphs with a minimum, seen in Refs. [8, 11, 27] and summarized by Fig. 8 in a recent review paper [2].

The dashed line denoted as the o plane is where the bound surface charge $\sigma_o$ resides, while the dashed line denoted as the d plane marks the beginning of the diffuse mobile layer, a layer stretching from the d plane to the bulk, and in which a mobile screening charge $\sigma_d$ resides. $C_s$ is the (Stern) capacitance of the immobile layer. The potentials at the o and d planes are denoted as $\phi_o$ and $\phi_d$, respectively.

For DI water with a saturated concentration of carbonate acid of 11.8 $\mu$M at 25 °C [50], pH = 5.68, in agreement with our own experimental measurements. Likewise, the salt KCl is represented by the potassium hydroxide family KOH, with charge states $z = 0$ and $+1$, together with the hydrochloric acid family HCl with charge states $z = 0$ and $-1$. A list of all involved chemical families taken into account in our model is shown in Table II.

When the total concentration $c_{X,z}^{\text{tot}}$ of each chemical family in a given aqueous solution is known, the equilibrium reactions listed in Table II can be solved with respect to the bulk concentration $c_{X,z}^{b}$ of each family member using the buffer calculator code [49]. This calculational scheme takes dissociation equilibrium, conservation of mass, and charge neutrality into account,

$$K_{X_z}c_{X,z}^{b}c_{X,z+1}^{b} = c_{X,z}^{b}c_{X,z+1}^{b}, \quad \text{dissociation reactions,} \quad (2a)$$

$$\sum_{z} c_{X,z}^{b} = c_{X}^{\text{tot}}, \quad \text{conservation of mass,} \quad (2b)$$

$$\sum_{X} c_{X,z}^{b} = 0, \quad \text{charge neutrality.} \quad (2c)$$

As Eqs. (2) describe the bulk ionic composition in the reservoirs, charge neutrality is a good approximation.

Once the bulk concentrations $c_{X,z}^{b}$ are known, three parameters characterizing the bulk electrolyte can be determined: the concentration of the involved $H^+$, $OH^-$, $HCO_3^-$, $CO_3^{2-}$, $K^+$, and $Cl^-$ ions in the reservoirs, (ii) surface reactions determining the potential and charge of the nanochannel surface, and (iii) the Poisson–Boltzmann equation for the potential and charge of the nanochannel.

Specifically, following Refs. [26, 33–44], we model the solid/liquid interface as the layered structure shown in Fig. 1. The innermost plane is the silica surface at the q plane with surface charge $\sigma_q$ and potential $\phi_q$. Next is the immobile Stern layer situated between the o plane and the d plane and having the capacitance $C_s$ [F/m$^2$]. Following the Stern layer is the diffusively charged screening layer extending from the d plane to the bulk and having surface charge $\sigma_d$ and $\zeta$ potential $\phi_d$. The last layer is the charge-neutral bulk of the reservoirs.

A. Bulk chemistry of the reservoirs

All bulk ionic concentrations in the reservoirs are calculated using the method of chemical families presented in Ref. [48] and supplemented by an open-source MATLAB-code buffer calculator [49]. For this paper, the carbonic acid family $H_2CO_3$ with charge states $z = 0$, $-1$, and $-2$ is of particular interest,

$$H_2CO_3 \rightleftharpoons HCO_3^- + H^+ \quad \text{pK}_{HCO_3} = 6.35, \quad (1a)$$

$$HCO_3^- \rightleftharpoons CO_3^{2-} + H^+ \quad \text{pK}_{CO_3^{2-}} = 10.33. \quad (1b)$$

As Eqs. (2) describe the bulk ionic composition in the reservoirs, charge neutrality is a good approximation.

For DI water with a saturated concentration of carbonate acid of 11.8 $\mu$M at 25 °C [50], pH = 5.68, in agreement with our own experimental measurements. Likewise, the salt KCl is represented by the potassium hydroxide family KOH, with charge states $z = 0$ and $+1$, together with the hydrochloric acid family HCl with charge states $z = 0$ and $-1$. A list of all involved chemical families taken into account in our model is shown in Table II.
TABLE II. List of the chemical families $X$ used in this paper together with the associated reaction schemes, charge states $z_X$, reaction constants $p K_{X,z_X}$, acid reaction action constants $p$, and electrophoretic mobilities $\mu_{X,z_X}^b$. Note that the $p K_{X,z_X}$ values are always associated with dissociation processes.

The total surface density of charge-active silanol sites at the wall is denoted as $\Gamma_{\text{tot}}$ [m$^{-2}$]. In our model, we take the three charge states $\Gamma_0 = 0$, $-1$, and $+1$ into account, for SiOH, SiO$^-$, and SiOH$_2^+$, respectively, as well as the two associated hydronium dissociation processes listed under silanol in Table II. These surface charge states have the densities $\Gamma_0$, $\Gamma_-$, and $\Gamma_+$, respectively, and it is natural to nondimensionalize them relative to $\Gamma_{\text{tot}}$ to obtain

$$\Gamma_0 = \frac{1}{\Gamma_{\text{tot}}} \Gamma_0, \quad \Gamma_- = \frac{1}{\Gamma_{\text{tot}}} \Gamma_-, \quad \Gamma_+ = \frac{1}{\Gamma_{\text{tot}}} \Gamma_+.$$  

with the obvious normalization condition

$$\Gamma_0 + \Gamma_- + \Gamma_+ = 1.$$  

The hydronium dissociation processes at the wall involve the concentration $c_H^b$ of the hydronium ions at the o plane, which, through the Boltzmann distribution, is related to the bulk concentration $c_H$. Consequently, the dimensional dissociation constants $K_{\pm}$ for the two surface processes as well as their nondimensionalized counterparts $\tilde{K}_{\pm} = K_{\pm} / c_H^b$ become

$$K_- = \frac{\Gamma_0}{\Gamma_-} c_H^b e^{-(e/k_B T) \phi_0}, \quad \tilde{K}_- = \frac{\Gamma_0}{\Gamma_-} e^{-\phi_0};$$

$$K_+ = \frac{\Gamma_0}{\Gamma_+} c_H^b e^{-(e/k_B T) \phi_0}, \quad \tilde{K}_+ = \frac{\Gamma_0}{\Gamma_+} e^{-\phi_0}.$$
The physical pK values pK± = −log10 (K±/1 M) are listed in Table II. The surface charge σo, and its nondimensionalized counterpart ˜σo normalized by eGtot are

\[ \sigma_o = e(\Gamma_+ - \Gamma_-), \quad \tilde{\sigma}_o = \tilde{\Gamma}_+ - \tilde{\Gamma}_-. \] (11)

Finally, by straightforward algebra combining Eqs. (9)–(11), we eliminate \( \tilde{\Gamma}_+ \), \( \tilde{\Gamma}_- \), and \( \tilde{\Gamma}_o \) and obtain an expression of \( \tilde{\sigma}_o \) in terms of \( \phi_0 \) and \( K_+ \),

\[ \tilde{\sigma}_o(\phi_0) = \frac{e^{-2\phi_0} - \tilde{K}_+ \tilde{K}_-}{e^{-2\phi_0} + \tilde{K}_+ e^{-\phi_0} + \tilde{K}_-}. \] (12)

### D. Relating the surface to the bulk

The above surface and bulk ionic concentrations can be coupled by the Poisson–Boltzmann equation. Whereas, hydronium ions can diffuse to the o plane, other ions may be coupled by the Poisson–Boltzmann equation. Whereas, the Poisson–Boltzmann equation (7) involve the surface charge \( \tilde{\sigma}_o \) and its nondimensionalized counterpart \( \tilde{\sigma}_o \). Finally, by straightforward algebra combining Eqs. (9)–(11), we eliminate \( \tilde{\Gamma}_+ \), \( \tilde{\Gamma}_- \), and \( \tilde{\Gamma}_o \) and obtain an expression of \( \tilde{\sigma}_o \) in terms of \( \phi_0 \) and \( K_+ \),

\[ \phi_0 - \phi_d = \frac{\sigma_o}{C_s}, \quad \tilde{\phi}_0 - \tilde{\phi}_d = \frac{\tilde{\sigma}_o}{C_s}, \quad \tilde{C}_s = \frac{k_B T}{e^2 G_{tot}} C_s. \] (13)

The boundary conditions at the surface for the Poisson–Boltzmann equation (7) involve the surface charge \( \tilde{\sigma}_o \) through Eqs. (12) and (13), and they become both nonlinear and mixed,

\[ n \cdot \nabla \tilde{\phi} = \frac{1}{\lambda_o} \tilde{\sigma}_o(\tilde{\phi}), \text{ at the d plane,} \] (14a)

\[ \tilde{q}_I = \frac{\sqrt{2 e k_B T}}{e^2 G_{tot}} c_I. \] (14b)

Here, we have introduced the surface normal \( n \) and the nondimensionalized bulk charge area density \( \tilde{q}_I \).

In the special case where the curvature effects of the boundary can be neglected, e.g., the tangential derivatives \( \nabla^2 \tilde{\phi} \) in \( \nabla^2 \tilde{\phi} \) are much smaller than the normal-direction derivatives \( \partial^2_{\tilde{\phi}} \), the Poisson–Boltzmann equation (7) can be integrated once. The standard trick is to multiply the equation by \( \partial_o \tilde{\phi} \), and then to use that \( (\partial_o \tilde{\phi}) \partial^2_{\tilde{\phi}} = \partial_o[(\partial_o \tilde{\phi})^2]/2 \) and \( -z_X(\partial_o \tilde{\phi}) \exp(-z_X \tilde{\phi}) = \partial_o[\exp(-z_X \tilde{\phi})] \). The result, known as Grahame’s equation \([55]\), is

\[ (\tilde{\sigma}_o)^2 = \tilde{q}_I^2 \sum \tilde{c}_{X=\pm} \left[ e^{-z_X \tilde{\phi}_0} - e^{-z_X \tilde{\phi}_n} \right], \] (15)

where \( \tilde{\phi}_m \) is the potential at the midpoint between opposite walls in the normal direction. In this simplified case, Eqs. (12), (13), and (15) form a self-consistent set of algebraic equations for the determination of \( \tilde{\sigma}_o \), \( \phi_0 \), and \( \phi_d \). This algebraic approach, in particular, can be employed for flat plane-parallel channels of a very large width-to-height aspect ratio, since in this case, the curvature effects only play a role for the vanishingly small region at the edges of the channel cross section.

### E. Entrance effects and permselectivity

For low salt concentration, the electric double layers of opposite walls of the nanochannel begin to overlap. Counterions are attracted to the nanochannel, while coions are expelled, and the nanochannel becomes permselective to the counterions. At each entrance of the nanochannel, the ionic densities have to attain their respective bulk values. This is achieved by displacing ions across the entrance, resulting in an ionic screening layer of width \( \lambda_D \) outside the entrance and uncompensated wall charges in the nanochannel, thus, creating oppositely pointing electric dipoles at each entrance and spanning the Donnan potential \([2]\). For low currents (the linear regime), no additional dissipation is created by this process: The potential drop experienced when passing into the nanochannel through one dipole region is canceled by the potential gain when leaving the nanochannel through the other dipole region.

The linear regime breaks down when a certain critical current \( I_c \), the so-called limiting current, is reached. In the limit of low flow velocities, \( I_c \) can be estimated by the classic Levich theory \([2,56,57]\) corrected by the logarithmic flux-focusing factor \([31]\),

\[ I_c = \frac{\pi}{\ln \left( \frac{\eta + 1}{\eta - 1} \right)} \frac{1}{2e A_{res} D c_I \nu}, \] (16)

where \( L_o \) is the distance from the nanochannel entrance to the electrode in the reservoir, \( 2h \) is the height of the nanochannel, \( \eta = I_c/L_o \) is the ratio of counterion and coion currents, \( e \) is the elementary charge, \( A_{res} \) is the reservoir cross-sectional area, \( D \) is the ionic diffusivity, and \( c_I \) is the strength of the solution in the reservoir.

For currents above \( I_c \), a finite-sized polarization concentration region with nearly zero ion concentration develops in front of the anode-side entrance of the nanochannel, and there will be a significant voltage drop across this region. When this happens, the measured conductance \( G \) of the system drops, and this more strongly for lower reservoir concentration, in stark contrast to the increased \( G \) observed on the low concentration side of the conductance minimum given by \( \delta \) in Table I and Eq. (21).

In Table III, we list the estimates for the limiting current \( I_c \) for low concentration (\( c_{KCl}^{\text{tot}} < 0.1 \text{ mM} \)) data points in Sec. IV B. In our experiments described in Sec. IV, we have

TABLE III. Estimates based on Eq. (16) of the limiting current \( I_c \) for data points in Sec. IV B with \( c_{KCl}^{\text{tot}} < 0.1 \text{ mM} \). \( A_{res} = 1.5 \text{ mm} \times 0.5 \text{ mm}, L_o = 0.75 \text{ mm}, \text{ and } D = 6 \times 10^{-9} \text{ m}^2/\text{s} \).
made sure that all our measurements were performed in the linear regime by using currents below 0.2 nA, i.e., at least a factor of 5 below the estimated limiting current $I_{\text{lim}}$. Therefore, the measured conductance is the intrinsic nanochannel conductance. Furthermore, by reversing the polarity, we have checked that no current rectification did take place (data not shown).

F. Nanochannel conductance

Operating under conditions where the entrance effects are negligible, the electrical conductance $G$ of an aqueous-filled nanochannel is found as $G = I/\Delta V$ by applying a known voltage drop $\Delta V$ and measuring the resulting current $I$. The electromigrative contribution $G_{\text{mig}} = I_{\text{mig}}/\Delta V$ to $G$ is found by integrating over the sum of the conductivities for the chemical families $X$. The external applied voltage also gives rise to an axial electric field $\Delta V/L$ driving an axial electro-osmotic flow $v(y,z)$ and resulting in an advective current $I_{\text{adv}}$ with the corresponding contribution, $G_{\text{adv}} = I_{\text{adv}}/\Delta V$, to the conductance. The flow is found by solving the steady-state Navier-Stokes equation with an electrical body force in a rectangular channel [58]. For high-aspect-ratio rectangular channels (height $2h$ much smaller than width $w$), only the vertical $z$ direction matters, and the explicit expression for the total conductance, $G = G_{\text{mig}} + G_{\text{adv}}$, is well approximated by

$$G = \frac{2ew}{L} \sum_{X,z} \sum_{X,z} \xi_X^{b} \xi_X^{c} \int_{-h}^{h} e^{-z\phi(z)} dz + \frac{2e\kappa b T w}{\eta L} \sum_{X,z} \sum_{X,z} \xi_X^{b} \xi_X^{c} \int_{-h}^{h} [\phi(z) - \tilde{\phi}_d] e^{-z\phi(z)} dz. \quad (17)$$

For zero internal potential ($\phi = 0$), the effects of the wall disappear, and we obtain the bulk conductivity $\sigma_{el}^b$ as

$$\sigma_{el}^b = e \sum_{X,z} \sum_{X,z} \xi_X^{b} \xi_X^{c} \xi_X^{c}. \quad (18)$$

III. NUMERICAL ONE-DIMENSIONAL ANALYSIS

In the following numerical analysis, we consider the case of a channel aligned with the $x$ axis and with a rectangular cross section in the $yz$ plane of height $2h$ and width $w$ such that $-h < z < h$ and $0 < y < w$, mimicking our experimental system described in Sec. IV. The width-to-height aspect ratio in this case is large, $w \gg 2h$ so that we can apply a one-dimensional (1D) approximation, where the side walls at $y = 0$ and $y = w$ can be neglected, and only the top and bottom walls at $z = \pm h$ play a role.

A. The numerical algorithm

The first part of our numerical scheme is using the buffer calculator [49] based on Eq. (2) to determine the bulk concentrations $c_X^{b} \xi_X^{c}$ for a given solution of the ions $H^+$, $OH^-$, $HCO_3^-$, $CO_3^{2-}$, $K^+$, and $Cl^-$. We then consider the self-consistent solution of Eqs. (12), (13), and (15), which, in this case, takes the form

$$\tilde{\sigma}_o = \tilde{C}_o (\tilde{\phi}_o - \tilde{\phi}_d). \quad (19a)$$

\[ \tilde{\sigma}_o = \frac{e^{-2z\phi}}{K_K} \tilde{K}_K \tilde{\phi}, \quad (19b) \]

\[ (\tilde{\sigma}_o)^2 = \tilde{q}_I \sum_{X,z} \xi_X^{b} \xi_X^{c} [e^{-z\phi} - e^{-z\phi}], \quad (19c) \]

\[ G = e^{-2z\phi} \tilde{K}_K \tilde{\phi}, \quad (19b) \]

\[ (\tilde{\sigma}_o)^2 = \tilde{q}_I \sum_{X,z} \xi_X^{b} \xi_X^{c} [e^{-z\phi} - e^{-z\phi}], \quad (19c) \]

together with the 1D Poisson–Boltzmann equation for planar walls including boundary conditions at the wall, $z = -h$, and at the center of the channel, $z = 0$,

$$\tilde{q}_I^2 \phi = - \frac{1}{2\lambda_o} \sum_{X,z} \xi_X^{b} \xi_X^{c} e^{-z\phi}, \quad (20a)$$

$$\tilde{q}_I \phi(-h) = \tilde{\phi}_d, \quad \tilde{q}_I \phi(0) = 0. \quad (20b)$$

We implement and solve the problem using MATLAB (Mathworks, Inc.) using the following self-consistent iteration algorithm:

Initialization: Calculate $pH = -\log_{10}(c_H^{b})$ and ionic concentrations $\xi_X^{b} \xi_X^{c}$ in the bulk using the buffer calculator [49] Eq. (2), and assume $\tilde{\phi}_m = 0$.

Loop: Solve Eq. (19) for $\tilde{\sigma}_o$, $\tilde{\phi}_o$, and $\tilde{\phi}_d$, then solve Eq. (20) for $\phi$ and, finally obtain $\tilde{\phi}_m = \tilde{\phi}_o(0)$.

Test: Repeat the loop until $\phi_m$ has converged.

Once converged, the algorithm provides the potential $\tilde{\phi}(z)$ to be used in Eq. (17) for calculating the conductance $G$. This algorithm, which self-consistently couples the CO$_2$-induced hydronium, surface, and bulk reactions, as well as nonlinear electrokinetics of the double layer, is the first main theoretical result of this paper.

B. Prediction of the conductance minimum

The second theoretical result is the model prediction that the conductance $G$ of a nanochannel depends monotonically on the KCl concentration $c_{\text{KCl}}^{\text{tot}} = c_{K^+}^{b} = c_{Cl^-}^{b}$ in the reservoirs. The nanochannel parameters listed in Table IV are chosen to correspond to our experimental validation presented in Sec. IV, and the simulation results are displayed in Fig. 2. Consistent with literature, the modeled conductance of the nanochannel follows a linear relation as does measured bulk conductance at high salt concentrations. Furthermore, the modeled conductance reaches a plateau in the infinite-dilution limit, similar to that found by Refs. [19,24,28,45]. However, as indicated in the log-log plot of Fig. 2(a) by the labels Plateau, Valley, Departure, and Bulk, we find, in contrast to these previous model studies, but in line with Ref. [32] where it went

\begin{table}[h]
\centering
\caption{List of the nanochannel parameters used in the model calculation of the nanochannel conductance, Fig. 2.}
\begin{tabular}{|c|c|c|}
\hline
Parameter & Symbol & Value \\
\hline
Height & $h$ & 165 nm \\
Width & $w$ & 8.3 \mu m \\
Length & $L$ & 12.0 mm \\
Surface site density & $\Gamma_{\text{wall}}$ & 5 nm$^{-2}$ \\
Stern capacitance & $C_s$ & 0.2 F m$^{-2}$ \\
Viscosity of water & $\eta$ & 1.0 mPa s \\
Permittivity of water & $\epsilon$ & 690 pF m$^{-1}$ \\
Temperature & $T$ & 298 K \\
\hline
\end{tabular}
\end{table}
un-noticed, that our model predicts a nonmonotonic behavior: A minimum conductance (the valley) is obtained before reaching the plateau. This conductance minimum positioned at $c_{\text{KCl}} = 10 \mu M$ is more clearly pronounced in the lin-log plot of Fig. 2(b). We quantify the magnitude of the conductance minimum as the ratio $\delta$ of the largest conductance $G_{\text{max}}$ on the low concentration side of the minimum and the minimum conductance $G_{\text{min}}$.

$$\delta = \frac{G_{\text{max}}}{G_{\text{min}}}. \quad (21)$$

For the KCl-based Fig. 2(b), we calculate $\delta_{\text{KCl}} = 1.42$.

In Fig. 2(c), we show how the calculated $\zeta$ potential $\phi_d$ and surface charge $\sigma_o$ vary with salt concentration, trends that have been previously theoretically observed and have been validated experimentally [26,44]. Moreover, as the magnitude of the $\zeta$ potential is small for our model system, $|\zeta| < 120 \text{ mV} \approx 5k_BT/e$, we have justified our neglecting of ionic crowding effects near the surface [59], and we gain confidence in our model results.

C. Characterization of the conductance minimum

Further results of our model showing nonmonotonic conductance vs the reservoir salt concentration $c_{\text{KCl}}$ are presented in Fig. 3, where parameters of the problem are varied one by one, relative to those of Fig. 2, which here and in the following are denoted $G_0$ (full black curve). In particular, when CO$_2$ is not included in our model (dashed red curve), the conductance changes by up to a factor of 2 relative to $G_0$. Additionally, without CO$_2$, the position of the conductance minimum shifts from $c_{\text{KCl}} \approx 10 \mu M$ down to $\approx 0.4 \mu M$ governed solely by autoprotolysis of water, again showing the importance of CO$_2$-induced hydronium ions for the appearance of nonmonotonic conductance.

In Fig. 3, we also plot $G$ of a solution with a lower ion mobility. Specifically, we substitute KCl with LiCl (dotted-blue curve), thereby reducing the counterion mobility by a factor of 0.53 from $\mu^+ = 76.2 \times 10^{-9} \text{ m}^2(\text{V s})^{-1}$ to $\mu^+ = 40.1 \times 10^{-9} \text{ m}^2(\text{V s})^{-1}$. Mobility reduction implies that: (i) In the high $c_{\text{KCl}}$ regime $\sim 10^{-3} - 10^{-1} \text{ M}$, the conductance is lower by a factor of $\sim 0.75$ consistent with the lower bulk conductivity of the LiCl electrolyte. (ii) In the very dilute $c_{\text{KCl}}$ regime $\sim 10^{-7} - 10^{-6} \text{ M}$, the conductance plateau reaches the same conductance value as KCl, again verifying that nanochannel conductance in this regime is dominated by the contribution from CO$_2$-induced hydronium. (iii) In the intermediate $c_{\text{KCl}}$ regime $\sim 10^{-6} - 10^{-3} \text{ M}$, the conductance curve has a different shape: The position of the minimum is shifted to a higher value of salt concentration, $c_{\text{KCl}} \approx 20 \mu M$, and its magnitude is increased from $\delta_{\text{KCl}} = 1.42$ to $\delta_{\text{LiCl}} = 1.77$. This enhancement of the conductance minimum for the lower-mobility counterion Li$^+$ is consistent with the intake of counterions and the expulsion of coions in nanochannels with overlapping electric double layers, a situation where the counterions dominate the conductance.

We also show the dependence of nanochannel height on the predominance of a nonmonotonic conductance at low concentrations in Fig. 3. Specifically, we reduce the height of the nanochannel by a factor of 0.18 to 2h$^* = 30 \text{ nm}$ (dot-dot-dashed green curve), corresponding to the silica
nanochannels of Ref. [60]. Again, we note that: (i) In the high
$\sigma_{\text{KCl}}^{\text{tot}}$ regime $\sim 10^{-3} - 10^{-1}$ M, the conductance is lower by a
factor of $\sim 0.18$ consistent with the reduced cross-sectional
area. (ii) In the intermediate $\sigma_{\text{KCl}}^{\text{tot}}$ regime $\sim 10^{-5} - 10^{-3}$ M, the conductance curve has a more linear slope and, therefore, a
wide regime of minimum conductance. (iii) In the very dilute
$\sigma_{\text{KCl}}^{\text{tot}}$ regime $\sim 10^{-7} - 10^{-5}$ M, the conductance is lower only by a
factor of $\sim 0.6$ and not by the aforementioned factor of 0.18. This relatively higher conductance in smaller channels
at low concentrations is due to overlapping electric double
layers. For a binary symmetric electrolyte, the conductivity
at low concentrations is due to overlapping electric double
layers. The smaller the channel dimensions, the greater the overlap, and, thus, the higher the average conductivity at a given low concentration. Note
that, for aid in comparing this low-height curve with the
nominal conductance curve, we also have plotted the scaled
version $G^* = 0.18 G_o$ (dotted black curve) of the original
curve.

These theoretical model predictions must now be verified
experimentally. To date, log-log plots of conductance vs salt
concentration in unbuffered solutions do not readily show
the conductance valley, but much of this may be because
such a valley is difficult to discern in a log-log plot, as
shown in Figs. 2 and 3. However, as listed in Table I, we
have found six examples in the literature of an observed

IV. EXPERIMENTAL VALIDATION

To test our theoretical predictions, we performed experi-
ments in both bulk solutions and fused-silica nanochannels
fabricated in-house at the University of California, Santa
Barbara [26]. The nanochannels (165-nm high, 8.3-μm wide, and
12-mm long) were equipped with 1.5-mm-diameter reservoirs
of depth 0.5 mm and mounted as shown in Fig. 4(a). We
prepared 0.2-μm-filtered KCl concentrations $c_{\text{KCl}}^{\text{tot}} = 0.0001$,
0.0003, 0.001, 0.003, 0.01, 0.025, 0.05, 0.1, 0.5, 1, 5, 10, and
100 mM and another set with 50 μM hydrochloric acid added
at the same KCl concentrations and at the additional values
$c_{\text{KCl}}^{\text{tot}} = 0.02, 0.2, 0.6, \text{and} 50 \text{mM}.$

A. Measured bulk conductance

To validate the bulk conductance part of our model, we
conducted bulk measurements using a standard technique: The
prepared solutions were pipetted into the sample chamber of

B. Measured nanochannel conductance

The nanochannel conductance was measured as follows.
After electrokinetically rinsing each channel thoroughly with
DI water three times, we applied five voltages to the system

FIG. 4. (Color online) Experimental measurement of current $I$
in silica nanochannels of dimensions $h \times w \times L = 165 \text{ nm} \times
8.3 \mu \text{m} \times 12 \text{ mm}$. (a) Our setup. For each experiment, the
voltage $\Delta V$ (from a Keithley 2410) was applied for 5–10 min to
allow $I$ to equilibrate (monitored by a high-sensitive electrometer,
Keithley 6517). (b) Raw data (dots) of $I$ vs sample number $N$ for
the five values of $\Delta V$ indicated. The inset shows detailed variation of
$I$ vs $N$ at 8 samples/s.

a commercial pH and conductivity meter (Oakton, Inc), and
readouts of the pH and conductivity values were performed
after allowing for equilibrium to have taken place. These
measurements were performed periodically on the prepared
solutions to make sure that variations due to temperature and
humidity did not exceed 5% of the original value. All solutions
were filtered with 0.2-μm PTFE syringe filters prior to use.

Figure 5(a) shows the measured bulk conductivity for the
KCl solutions used in our study, together with two model
calculations of $\sigma_{\text{KCl}}^{\text{tot}}$ based on Eq. (18) and Table II without any
additional adjustable parameters: one (full line) taking into
account all ions (H$^+$, OH$^-$, HCO$_3^-$, CO$_3^{2-}$, K$^+$, Cl$^-$), the other
(dashed line) only including the salt (K$^+$, Cl$^-$). Both measure-
ments and model calculations show the expected monotonic
decrease as a function of the bulk KCl concentration $c_{\text{KCl}}^{\text{tot}}$
with a crossover to a constant value at $c_{\text{KCl}}^{\text{tot}} \approx 5 \times 10^{-6}$ M.
The inset shows a scatter of the measurements relative to
the model with errors within 13%, which, thus, constitutes
an estimate of the experimental uncertainty in our paper.
To further test the model, we added 50-μM HCl to our
KCl solutions; experimental results and model calculation are
shown in Fig. 5(b), with the inset indicating the deviation of
measurements relative to the model to be within 16%.
FIG. 5. (Color online) (a) Conductivity $\sigma_{\text{bulk}}$ vs KCl concentration $c_{\text{tot}}^{\text{KCl}}$ for bulk measurements ($\sigma_{\text{meas}}^{\text{bulk}}$, open red circles) and model calculations for both the full model with KCl, H$_2$CO$_3$, and H$_2$O ($\sigma_{\text{mod}}^{\text{full}}$, full line) and for a partial model with only KCl (dashed line). Model calculations are based on Eq. (18) and Table II without any additional adjustable parameters. The inset shows the relative deviation $X = (\sigma_{\text{meas}}^{\text{bulk}} - \sigma_{\text{mod}}^{\text{full}})/\sigma_{\text{mod}}^{\text{full}}$ (open blue circles) of the measurements from the model. (b) Same as panel (a) with the addition of 50-$\mu$M HCl. (100, 200, 300, 400, and 500 V) in succession, each one lasting approximately 40 s. Raw data are shown in Fig. 4(b). To ensure consistent and repeatable data, if the trial did not yield four or five results that were within 10% of each other, we assumed an unsteady current reading, corroded electrodes, external interference, or poor channel preparation, and discarded the data. Solution exchanges were performed in a systematic fashion to avoid introducing bubbles or particulate matter into the channels.

Moreover, for concentrations below 10 $\mu$M, we covered the system with a Faraday cage to limit measurement noise. After each day of experiments, we flushed the reservoirs multiple times with DI water to prevent a buildup of salt deposits on the channel during its time in storage, and then stored the chip in a dry Eppendorf tube housed in a nitrogen container. We note that electrolysis does not affect the current measurements in our system: Conservatively, we estimate the pH change of the reservoir to be $7.7 \times 10^{-4}$ s$^{-1}$ [48]; next, we find the volumetric flow rate to be $4 \times 10^{-15}$ m$^3$/s; furthermore, the absorption of CO$_2$ in the reservoir gives rise to H$_2$CO$_3$, which acts as a buffer and would further prevent pH changes, and finally, we replenished the reservoirs every 3 min.

Due to a significant electro-osmotic flow velocity in our 165-nm-high nanochannels, we do not encounter the hour-long equilibration time for conductance measurements encountered in 2-nm-high nanochannels [32].

The most significant contribution of our model is predicting the nanochannel conductance, which is shown together with experimental measurements in Fig. 6. Panel (a) shows results for KCl solutions between infinite dilution (DI water) and 100 mM. Using $pK_-$ as the only fitting parameter, and using $\log_{10}(c_{\text{tot}}^{\text{KCl}})$ and $\log_{10}(G)$ as variables to ensure an even weighting between low and high concentration values, we

FIG. 6. (Color online) Log-log plot of measured nanochannel conductance $G$ vs KCl concentration $c_{\text{tot}}^{\text{KCl}}$ (red circles) and curve fits based on Eq. (17) using the logarithmic variables $\log_{10}(G)$ and $\log_{10}(c_{\text{tot}}^{\text{KCl}})$ for model electrolytes of various compositions (full and dashed curves) employing the parameters of Tables II and IV. (a) No HCl added: Fitting to a model including KCl, H$_2$O, and H$_2$CO$_3$ (full curve) yields $pK_- = 6.56 \pm 0.06$. Also shown is a model calculation including only KCl (dashed line). (b) As before but with 50 $\mu$M of HCl added: Fitting to a model including KCl, HCl, H$_2$O, and H$_2$CO$_3$ (full curve) yields $pK_- = 6.91 \pm 0.10$. The insets are lin-log plots of the respective low salt concentration regions.
obtain the fit shown for pH = 6.56 ± 0.06, corresponding well to the literature value of 6.64 [44]. The inset expands on the low salt concentration region and shows the measured conductance minimum and the theoretical fitting curve. The lowest concentration point is furthest off this curve, but it is also the one most prone to error. Previous models assuming constant surface charge give the plateau but no valley [19,24, 28,45], while relaxing this assumption taking surface chemical reactions into account leads to a monotonically decreasing conductance [61]. Notably, the experimental data of previous studies listed in Table I, have shown the same conductance behavior as our model and data, supporting our claim that the inclusion of hydronium ions in our model is consistent with a behavior as our model and data, supporting our claim that the equilibrium dissociation scheme. Using this model, we have predicted the hydronium dependence of the electrical conductance of electrolyte-filled nanochannels, and, in particular, we have identified a conductance minimum in the low salt concentration regime as a function of the reservoir salt concentration $c_{KCl}$. We studied the dependence of the conductance minimum theoretically and have predicted that its magnitude would be reduced dramatically in a CO2-poor atmosphere and significantly enhanced using low-mobility counterions.

Our theoretical prediction of the conductance minimum is supported by several independent experimental observations in the literature. Furthermore, to validate our theoretical predictions, we have successfully compared our model with direct experimental conductance measurements on a wide range of KCl concentrations with and without the addition of a specific extra amount of hydronium ions from HCl in 165-nm high silica nanochannels. A more thorough experimental study is underway to fully characterize the nanochannel conductance minimum at low salt concentrations and CO2-dissolution controlled hydronium concentrations.

Our modeling and experimental results indicate the possibility for developing a sensitive nanochannel-based carbon dioxide sensor. To this end, an in-depth experimental study must be performed in a tightly regulated atmosphere. Combining such measurements with our model could be used to determine which parameter values lead to the most pronounced conductance minimum and which consequences this may have for using nanochannels for unique gas sensors.

[50] This value follows from Henry’s law with the coefficient \(c_{CO_2(aq)} / P_{CO_2(g)} = 3.5 \text{mM/ atm} \) [51] for CO \(_2\) \(\rightleftharpoons CO_2(aq)\) and the reaction constant \(K_{H_2CO_3} = 2.6 \times 10^{-3} \) for carbonic acid \(H_2O + CO_2(aq) \rightleftharpoons H_2CO_3\) [48].
